MEDINFO 2017: PRECISION HEALTHCARE THROUGH INFORMATICS
Studies in Health Technology and Informatics

This book series was started in 1990 to promote research conducted under the auspices of the EC programmes’ Advanced Informatics in Medicine (AIM) and Biomedical and Health Research (BHR) bioengineering branch. A driving aspect of international health informatics is that telecommunication technology, rehabilitative technology, intelligent home technology and many other components are moving together and form one integrated world of information and communication media. The series has been accepted by MEDLINE/PubMed, SciVerse Scopus, EM Care, Book Citation Index – Science and Thomson Reuters’ Conference Proceedings Citation Index.

Series Editors:

Welcome to MedInfo2017

On behalf of the Editorial Committee (EC) for MedInfo2017, please accept our warm welcome to Hangzhou to celebrate the art and science of informatics in a truly breath-taking venue and with colleagues from around the world.

Learning from the experience of prior chairs

Learning from prior work and the experience of those who walked the path before is invaluable when embarking on a new venture. The first emails and calls after receiving word of my nomination to be EC chair were to prior chairs Christoph U. Lehmann (MedInfo2013) and Indra Neil Sarkar (MedInfo2015). While assuring me that this was a task that could be done (as they had so wonderfully demonstrated!), they did tell me that it was a huge effort that would take time, resources, and patience. It would be worth all the effort, they added. I am grateful to them for their guidance and gracious sharing of their experiences and lessons learned.

The journey

Starting with assisting the Scientific Program Committee (SPC) to bring out the call for papers, to witnessing the submissions start to come in as a trickle and end with an avalanche, to planning and executing the copy editing and formatting of the accepted papers and posters, the journey has been an interesting one to say the least.

First, let me start by saying what a great opportunity it has been to serve the international informatics community through MedInfo2017. It is an extraordinary honor to be able to chair the EC and I am grateful to the leadership of MedInfo2017 and the International Medical Informatics Association (IMIA) for their trust in me.

Second, I must acknowledge that it has truly been a great experience, as my predecessors had indicated it would be. Conceptualizing and executing the process of copy editing and formatting of nearly 400 five-page papers and one-page posters is a daunting task. I was ably assisted by two senior associate editors who are two amazing informatics students and rising stars in the field: Shauna Overgaard (University of Minnesota) and Kate Fultz Hollis (Oregon Health & Science University). Brainstorming, planning, and finally executing the work of the EC became a pleasure and I looked forward to our weekly conference calls to assess progress and resolve issues.

Third, working with Shauna and Kate, we recruited 41 outstanding associate editors (AEs) who then set out to copy edit and check the formatting of the accepted submissions. We set-up a multi-phase, cross-over plan wherein one AE would perform the editing and formatting and later another AE would review the work and revise as needed. The third phase involved the senior AEs reviewing the submissions and finally, I personally reviewed each and every submission and then finalized the documents for the proceedings.

The editorial task is not trivial; the authors represent all continents (except Antarctica), and hail from varied backgrounds and professions, stages of training and career, and thereby epitomize a wide-range of experience in our field. Imagine a multifaceted channel in which technical research findings are communicated, by diverse researchers, often through a language barrier, to a diverse audience, who have been instructed to write academically in the official language of MedInfo (English). Now, add to that the requirement to adhere to a strict template (that is of paramount importance for uniformity and layout for the publishers). Indeed, this sets the stage for our work. But, be certain that it is undeniably humbling to experience the breadth, depth, and quality of the work presented by authors at MedInfo2017 and the proficiency with which their findings are communicated to an international audience.

The credit for preparing the submissions for the official conference proceedings goes to the the AE team, the senior AEs, and the Editorial Committee. Even through a process where at least four individuals have reviewed a submission, it is possible that we may have missed a word here or formatting there. We offer our apologies for any inadvertent errors in the final proceedings.

The final stretch

It truly takes a village to complete such a large task. We acknowledge and thank the publishers, IOS Press, for their work on the proceedings. Paul Weij has been a great ally in this venture: offering advice and guidance on the technical aspects and being patient with us while we asked many questions and ultimately delivered the final files. Our thanks to the entire IOS Press team for their professional work and service with a smile. The VP of MedInfo2017, Kaija Saranto, has been an ardent supporter from the beginning. The SPC co-chairs, Elizabeth Borycki and Niels Peek, have been invaluable in their support and gracious with their advice in helping the EC complete its work. A special thanks and shout-out to Elaine Huesing, CEO, IMIA for her help in counseling and patiently guiding me through the work of the EC. Our thanks to Yonggin Huang (Chair), Emmett Huang (Vice-Chair), and the entire local organizing committee for their guidance in finalizing the proceedings. Our thanks to the two EC members, Dongsheng Zhao (China) and Marie-Christine Jaulent (France) for their involvement and culturally appropriate advice. And finally, listed in Table 1 are the AEs that spent countless hours reviewing, formatting, and copy-editing the nearly 400 papers and posters that make up the official MedInfo2017 conference proceedings.
As this editing experience carries prestige, is an enjoyable challenge, and is highly valuable for the CV, several members of the team have served as AEs for two and even three years. They have our gratitude and the satisfaction of having contributed to a worthy academic venture that will be read and cited for years to come. We have learned a few more lessons to add to the playbook created many years ago by our predecessors.

To the next MedInfo team, we wish you good luck and you know where to find us.

With warm regards and best wishes for a productive and successful MedInfo2017,

Adi V. Gundlapalli, MD, PhD, MS
Chair, Editorial Committee

From the Scientific Program Chairs

Elizabeth M. Borycki\textsuperscript{a}, Niels Peek\textsuperscript{b}

\textsuperscript{a}School of Health Information Science, University of Victoria, Victoria, British Columbia, Canada
\textsuperscript{b}Health eResearch Centre, University of Manchester, Manchester, United Kingdom

The 16\textsuperscript{th} World Congress of Medical and Health Informatics: Precision Healthcare through Informatics (MedInfo2017) was held in Hangzhou, China from August 21\textsuperscript{st} to 25\textsuperscript{th}, 2017, and celebrated the International Medical Informatics Association’s (IMIA) 50\textsuperscript{th} Anniversary. The conference was jointly hosted by IMIA and the Chinese Medical Informatics Association (CMIA).

China Medical Informatics Association

CMIA was established in 1980 and has provided over 37 years of leadership with its experts, scholars and managers leading and advancing medical informatics research and health information technologies in China and internationally. CMIA has over 6200 members, 115 directors, 18 regional branches, and 29 professional activities. CMIA draws its support from a broad and diverse group of organizations: the government, education, health and family planning, food and drug administration and traditional Chinese medicine ministries. We thank CMIA, its directors, professional groups and members for their support and their hosting of MedInfo2017. We would also like to thank the Local Organizing Committee of MedInfo2017 for their hard work in organizing this outstanding conference.

MedInfo2017

The central theme of MedInfo2017 was “Precision Healthcare through Informatics”, and alludes to the rapidly increasing opportunities to support customization of healthcare to the individual patient using the power of data and informatics. The scientific program was built up across five tracks: Connected and Digital Health; Human Data Science; Human, Organizational and Social Aspects; Knowledge Management and Quality, and Safety and Patient Outcomes.

We received 680 submissions (papers; posters; tutorials; panels; and workshops) from over 50 countries from all IMIA regions. The submissions spanned sub-disciplines in biomedical and health informatics such as clinical informatics, nursing informatics, consumer health informatics, public health informatics, human factors in health care, bioinformatics, translational informatics, quality and safety and research at the intersection of biomedical and health informatics, and precision medicine. After a thorough review process we accepted 249 papers, 168 posters, 18 tutorials, 23 panels, and 25 workshops. Each submission was reviewed independently by at least three reviewers, and subsequently assessed by one of the Scientific Program Committee (SPC) members and one of the SPC Track Chairs. Thus we ensured that all our decisions were well-informed and helped to create a program that is balanced across topics and has strong representation from all IMIA regions.

Paper and poster submissions are included in these proceedings.

The conference also featured four keynote lectures given by researchers who are renowned for their work worldwide. Depei Liu from China is a leading researcher in area of data sharing in population health and the population link to health, science and technology. Harry Hemingway is conducting research in the United Kingdom, focused on innovating health and health care improvement through the use of data from life long patient records. Sue Bakken from the United States is presenting on research in the area of precision self-management. Lastly, Chris Seebregts leads several projects in the area of open medical health records and health information exchange focusing on how these technologies can be used to support public health system and reduce the burden of disease.

We would like to thank the Scientific Program Track Chairs, members, and the reviewers for their valuable contributions in creating the MedInfo2017 scientific program. We would also like to thank all contributors to MedInfo2017 without whom we would not be able to advance the science, education and practice of biomedical and health informatics globally.

International Medical Informatics Association

The International Medical Informatics Association (IMIA) celebrated its 50\textsuperscript{th} Anniversary with MedInfo2017 in Hangzhou, China. IMIA has brought together academics, researchers and practitioners of biomedical and health informatics from around the world. It has lead to the creation of a discipline and a field of study and education that is present in every country around the world. IMIA’s global reach is significant and its leadership, through its members has lead to the modernization of health care through information technology and to the support of citizens and health professionals use of technology throughout the world.

Congratulations IMIA on your 50\textsuperscript{th} Anniversary and we look forward to the next 50 years moving forward!

Sincerely,

Elizabeth Borycki, RN, PhD and Niels Peek, MSc, PhD

MedEx/J: A One-Scan Simple and Fast NLP Tool for Japanese Clinical Texts
Eiji Aramaki, Ken Yano and Shoko Wakamiya

Locally Adaptive Operators for Red Lesions Detection in Eye Fundus Images
Luiza Dri Bagesteiro, Daniel Welfer, Marcos Cordeiro d’Ornellas, Juliano F. Kazienko, Carlos Jesus Pereira Haygert and Gustavo Nogara Dotto

Semi-Automatic Mark-Up and UMLS Annotation of Clinical Guidelines
Matthias Becker and Britta Böckmann

Inter-Annotator Agreement and the Upper Limit on Machine Performance: Evidence from Biomedical Natural Language Processing
Mayla Boguslav and Kevin Bretonnel Cohen

Sharing Health Big Data for Research – A Design by Use Cases: The INSHARE Platform Approach
Guillaume Bouzillé, Richard Westerlynck, Gauthier Defossez, Dalel Bouslimi, Sahar Bayat, Christine Riou, Yann Busnel, Clara Le Guillou, Jean-Michel Cauvin, Christian Jacquelin, Patrick Pladys, Emmanuel Oger, Eric Stindel, Pierre Ingrand, Gouenou Coatrieux and Marc Cuggia

Developing Visual Thinking in the Electronic Health Record
Andrew D. Boyd, Christine D. Young, Margret Amatayakul, Michael G. Dieter and Lawrence M. Pawola

What Information Does Your EHR Contain? Automatic Generation of a Clinical Metadata Warehouse (CMDW) to Support Identification and Data Access Within Distributed Clinical Research Networks
Philipp Bruland, Justin Doods, Michael Storck and Martin Dugas

Automatic Identification of Glaucoma Using Deep Learning Methods
Allan Cerentini, Daniel Welfer, Marcos Cordeiro d’Ornellas, Carlos Jesus Pereira Haygert and Gustavo Nogara Dotto

Mining Adverse Drug Reactions in Social Media with Named Entity Recognition and Semantic Methods

Predicting Adverse Outcomes in Heart Failure Patients Using Different Frailty Status Measures
Yan Cheng, Yijun Shao, Charlene R. Weir, Rashmee U. Shah, Bruce E. Bray, Jennifer H. Garvin and Qing Zeng-Treitler

A Data-Driven Decision-Support Tool for Population Health Policies
Michal Chorev, Lavi Shpigelman, Peter Bak, Avi Yaeli, Edwin Michael and Ya’ara Goldschmidt

The Pluripotent Rendering of Clinical Data for Precision Medicine
Christopher G. Chute and Stanley M. Huff

Classification of Clinical Research Study Eligibility Criteria to Support Multi-Stage Cohort Identification Using Clinical Data Repositories
James J. Cimino, William J. Lancaster and Mathew C. Wyatt

Translational Morphosyntax: Distribution of Negation in Clinical Records and Biomedical Journal Articles
K. Bretonnel Cohen, Foster R. Goss, Pierre Zweigenbaum and Lawrence E. Hunter
Extracting Sexual Trauma Mentions from Electronic Medical Notes Using Natural Language Processing
Guy Divita, Emily Brignone, Marjorie E. Carter, Ying Suo, Rebecca K. Blais, Matthew H. Samore, Jamison D. Fargo and Adi V. Gundlapalli

General Symptom Extraction from VA Electronic Medical Notes
Guy Divita, Gang Luo, Le-Thuy T. Tran, T. Elizabeth Workman, Adi V. Gundlapalli and Matthew H. Samore

An Integrated Surveillance System to Examine Testing, Services, and Outcomes for Sexually Transmitted Diseases
Brian E. Dixon, Guoyu Tao, Jane Wang, Wanzhu Tu, Sarah Hoover, Zuoyi Zhang, Teresa A. Batteiger and Janet N. Arno

Development and Validation of Various Phenotyping Algorithms for Diabetes Mellitus Using Data from Electronic Health Records
Santiago Esteban, Manuel Rodriguez Tablado, Francisco Peper, Yamila S. Mahumud, Ricardo I. Ricci, Karin Koptitowski and Sergio Terrasa

Detecting Signals of Interactions Between Warfarin and Dietary Supplements in Electronic Health Records
Yadan Fan, Terrence J. Adam, Reed McEwan, Serguei V. Pakhomov, Genevieve B. Melton and Rui Zhang

From Bench to Bedside: A View on Bioinformatics Pipelines
Blanca Flores, Dirk Hose, Anja Seckinger, Petra Knaup and Matthias Ganzinger

A Personalized Adviser-Interpreter System for Monitoring Diabetic Patients’ Weight Loss
Azadeh Kamel Ghalibi and Seyed Mahmoud Tara

An Infrared Thermal Images Database and a New Technique for Thyroid Nodules Analysis
José R. González, Charbel Damido and Aura Conci

Automatically Identifying Topics of Consumer Health Questions in Chinese
Haihong Guo, Xu Na and Jiao Li

Detecting Protected Health Information in Heterogeneous Clinical Notes
Aron Henriksson, Maria Kvist and Hercules Dalianis

Acute Coronary Syndrome Risk Prediction Based on GRACE Risk Score
Dangqing Hu, Zhengxiong Huang, Tak-Ming Chan, Wei Dong, Xudong Lu and Hualong Duan

Prediction and Factor Extraction of Drug Function by Analyzing Medical Records in Developing Countries
Min Hu, Yasunobu Nohara, Masafumi Nakamura and Naoki Nakashima

Conditional Density Estimation of Tweet Location: A Feature-Dependent Approach
Hayate Iso, Shoko Wakanijya and Eiji Aramaki

Analysis of the Existence of Patient Care Team Using Social Network Methods in Physician Communities from Healthcare Insurance Companies
Márcia Ito, Ana Paula Appel, Vagner Figueiredo de Santana and Luís G. Moyano

Measurement of Respiration Rate and Depth Through Difference in Temperature Between Skin Surface and Nostril by Using Thermal Image
Hieyong Jeong, Yutaka Matsuura and Yuko Ohno

Visualizing Article Similarities via Sparsified Article Network and Map Projection for Systematic Reviews
Xiaoran Ji, Raghu Machiraju, Alan Ritter and Po-Yin Yen

A Hybrid Method for ICD-10 Auto-Coding of Chinese Diagnoses
Zheng Jia, Weifeng Qin, Hui-long Duan, Xudong Lv and Haomin Li

The Impact of “Possible Patients” on Phenotyping Algorithms: Electronic Phenotype Algorithms Can Only Be Reproduced by Sharing Detailed Annotation Criteria
Rina Kagawa, Yoshimasa Kawazoe, Emiko Shinohara, Takeshi Imai and Kazuhiko Ohe

Analysis of Historical Medical Phenomena Using Large N-Gram Corpora
Zdenko Kasač and Stefan Schulz

An Incremental Adoption Pathway for Developing Precision Medicine Based Healthcare Infrastructure for Underserved Settings
Suranga N. Kasithurirathne, Paul G. Biondich, Burke W. Maml, Theresa A. Cullen and Shaun J. Grannis
Diagnostic Machine Learning Models for Acute Abdominal Pain: Towards an e-Learning Tool for Medical Students
Piyapong Khumrin, Anna Ryan, Terry Judd and Karin Verspoor

Developing Methodologies to Find Abbreviated Laboratory Test Names in Narrative Clinical Documents by Generating High Quality Q-Grams
Kyungmo Kim and Junwook Choi

Characterising the Scope of Exposome Research: A Generalisable Approach
Philip Kiousoglou, Ann Borda, Kathleen Gray, Fernando Martin-Sanchez, Karin Verspoor and Guillermo Lopez-Campos

Creation of the First French Database in Primary Care Using the ICPC2: Feasibility Study
V. Lacroix-Hugues, D. Darmon, C. Predier and P. Staccini

Conversion of National Health Insurance Service-National Sample Cohort (NHIS-NSC) Database into Observational Medical Outcomes Partnership-Common Data Model (OMOP-CDM)
Seng Chan You, Seongwon Lee, Soo-Yeon Cho, Hojun Park, Sungjae Jung, Jaehyeong Cho, Dukyong Yoon and Rae Woong Park

Assessing Data Integration and Quality for the Evaluation of Point-of-Care Testing Across Rural and Remote Emergency Departments in Australia
Lin Li, Euan McCaughhey, Juliana Iles-Mann, Andrew Sargeant, Maria R. Dahm, Virginia Mumford, Johanna I. Westbrook and Andrew Georgiou

Using Machine Learning Models to Predict In-Hospital Mortality for ST-Elevation Myocardial Infarction Patients
Xiang Li, Haiying Liu, Jingang Yang, Guotong Xie, Meilin Xu and Yuejin Yang

Extracting Eligibility Criteria from the Narrative Text of Scientific Research Articles
Ching-Yun Lin, Der-Ming Liou and Mei-Lien Pan

Assessing the Representation of Occupation Information in Free-Text Clinical Documents Across Multiple Sources
Elizabeth A. Lindemann, Elizabeth S. Chen, SriPriya Rajamani, Nivedha Manohar, Yan Wang and Genevieve B. Melton

Precision Cohort Finding with Outcome-Driven Similarity Analytics: A Case Study of Patients with Atrial Fibrillation
Haifeng Liu, Xiang Li, Guotong Xie, Xin Du, Ping Zhang, Chengming Gu and Jingyi Hu

Biomedical Informatics and the Digital Component of the Exposome
Guillermo Lopez-Campos, Mark Meroll and Fernando Martin-Sanchez

Enhanced LexSynonym Acquisition for Effective UMLS Concept Mapping
Chris J. Lu, Destinee Tormey, Lynn McCriddy and Allen C. Browne

A Validated Risk Model for 30-Day Readmission for Heart Failure
Satish M. Mahajan, Prabir Burman, Ana Newton and Paul A. Heidenreich

CrowdMapping: A Crowdsourcing-Based Terminology Mapping Method for Medical Data Standardization
Huqian Mao, Chenyang Chi, Boyu Huang, Haibin Meng, Jinghui Yu and Dongsheng Zhao

Case Report Form Reporter: A Key Component for the Integration of Electronic Medical Records and the Electronic Data Capture System
Yasushi Matsumura, Atsushi Hattori, Shiro Manabe, Daiyo Takahashi, Yuichiro Yamamoto, Taizo Murata, Akito Nakagawa, Naoki Mihara and Toshihiro Takeda

Scholarly Information Extraction Is Going to Make a Quantum Leap with PubMed Central (PMC)*—But Moving from Abstracts to Full Texts Seems Harder than Expected
Franz Matthies and Udo Hahn

Can Sonification Become a Useful Tool for Medical Data Representation?
George I. Mihalas, Minodora Andor, Anca Tudor and Sorin Paralescu

Constructing a Gene-Drug-Adverse Reactions Network and Inferring Potential Gene-Adverse Reactions Associations Using a Text Mining Approach
MingShuang Sui and Lei Cui

Establishment of New National Rare Disease (Nambyo) Registry and Registry Guidelines in Japan
Hiroshi Mizushima, Mai Tanabe, Yasutaka Suganori, Yoko Sato and Hiromitsu Ogata

xx

Diagnose Machine Learning Models for Acute Abdominal Pain: Towards an e-Learning Tool for Medical Students
Piyapong Khumrin, Anna Ryan, Terry Judd and Karin Verspoor

Developing Methodologies to Find Abbreviated Laboratory Test Names in Narrative Clinical Documents by Generating High Quality Q-Grams
Kyungmo Kim and Junwook Choi

Characterising the Scope of Exposome Research: A Generalisable Approach

Creation of the First French Database in Primary Care Using the ICPC2: Feasibility Study
V. Lacroix-Hugues, D. Darmon, C. Predier and P. Staccini

Conversion of National Health Insurance Service-National Sample Cohort (NHIS-NSC) Database into Observational Medical Outcomes Partnership-Common Data Model (OMOP-CDM)
Seng Chan You, Seongwon Lee, Soo-Yeon Cho, Hojun Park, Sungjae Jung, Jaehyeong Cho, Dukyong Yoon and Rae Woong Park
Unsupervised Abbreviation Expansion in Clinical Narratives  
Michel Oleynik, Markus Kreuzthaler and Stefan Schulz  

Contrast Mining for Pattern Discovery and Descriptive Analytics to Tailor Sub-Groups of Patients Using Big Data Solutions  
Michael A. Pinney, Yan Zhuang, Sean Lander, Lincoln Sheets, Jerry C. Parker and Chi-Ren Shyu  

Detecting Adverse Drug Event Signals from a Clinical CaseBase  
Weifeng Qin, Xian Zeng, Zheng Jia, Xiang Zheng, Huilong Duan, Xudong Lu and Haomin Li  

Extraction of Data from a Hospital Information System to Perform Process Mining  
Ricardo Alfredo Quintana Neira, Gert-Jan de Vries, Jennifer Cañafar and Erin Stretton  

Development of a Deep Learning Algorithm for Automatic Diagnosis of Diabetic Retinopathy  
Manoj Raju, Venkatesh Pagidimarri, Ryan Barreto, Amrit Kadam, Vamsichandra Kasivajjala and Arun Aswath  

Envisioning Precision Healthcare Informatics: A Unified Framework  
Arkalgud Ramaprasad, Nanda Kumar Bidare Sastry and Thant Syn  

A Virtual Earth Model of the Dementias in China  
Hamish Robertson, Nick Nicholas, Jo Travaglia, Andrew Hayen and Andrew Georgiou  

Comparison of Regression Analysis and Transfer Function in Estimating the Parameters of Central Pulse Waves from Brachial Pulse Wave  
Rui Chai, Li-sheng Xu, Yang Yao, Li-ling Hao and Lin Qi  

Longitudinal Changes in Risk Stratification for a Managed Population  
Lincoln Sheets, Mihail Popescu, Kayson Lyttle, Soo-Yeon Cho and Jerry C. Parker  

Phenotypic Analysis of Clinical Narratives Using Human Phenotype Ontology  
Feichen Shen, Liwei Wang and Hongfang Liu  

The Study of Pulse Condition of Traditional Chinese Medicine in Information Age  
Cheng Shi, Yu Zhang, Qingyue Gong, Jinhai Zhou and Lisheng Xu  

Automated Evaluation System for Human Pupillary Behavior  
Cleyton Rafael Gomes Silva, Cristhiane Gonçalves, Eduardo N.R. Camilo, Fabio Boaretto dos Santos, Joyce Siqueira, Eduardo Simões de Albuquerque, Fabrizzio Alphonsus Alves de Melo Nunes Soares, Leandro Luís Galdino de Oliveira and Ronaldo Martins da Costa  

Prescription Opioid Dependence in Western New York: Using Data Analytics to Find an Answer to the Opioid Epidemic  
Shyamashree Sinha, Gale R. Burstein, Kenneth E. Leonard, Timothy F. Murphy and Peter L. Elkin  

Phenotyping and Visualizing Infusion-Related Reactions for Breast Cancer Patients  
Deyu Sun, Gopal Sarda, Steven J. Skabe, Anne H. Blaes, Saif Khairat, Genevieve B. Melton and Rui Zhang  

A Deep Learning-Based Method for Similar Patient Question Retrieval in Chinese  
Guo Yu Tang, Yuan Ni, Guo Tong Xie, Xin Li Fan and Yan Ling Shi  

Automating the Identification of Patient Safety Incident Reports Using Multi-Label Classification  
Ying Wang, Enrico Coiera, William Runciman and Farah Magrabi  

Mining Adverse Events of Dietary Supplements from Product Labels by Topic Modeling  
Yefeng Wang, Divya R. Gunashekar, Terrence J. Adam and Rui Zhang  

An Early Infectious Disease Outbreak Detection Mechanism Based on Self-Recorded Data from People with Diabetes  
Ashenafi Zebene Woldaregay, Eirik Àrsand, Taxiaarchis Botsis and Gunnar Hartvigsen  

Uncovering Hidden Topics in Hong Kong Clinical Research Through Hospital Authority Convention Publications  
Zoie Shui-Yee Wong, Wai-Man Chan, Eliza Lai-Yi Wong, Patsy Yuen-Kwan Chau, Kwok-Leung Tsui and Hong Fung  

Aligned-Layer Text Search in Clinical Notes  
Stephen Wu, Andrew Wen, Yanshan Wang, Sijia Liu and Hongfang Liu  

A Bayesian Network Model of Head and Neck Squamous Cell Carcinoma Incorporating Gene Expression Profiles  
Shuyang Wu, Anthony Law and Mark E. Whipple
Applying Risk Models on Patients with Unknown Predictor Values: An Incremental Learning Approach
Enliang Xu, Xiang Li, Jing Mei, Shiwan Zhao, Gang Hu, Eryu Xia, Haifeng Liu, Guotong Xie, Meilin Xu and Xuejun Li 639

Semantic Relations in Compound Nouns: Perspectives from Inter-Annotator Agreement
Prabha Yadav, Elisabetta Jezek, Pierrette Bouillon, Tiffany J. Callahan, Michael Bada, Lawrence E. Hunter and K. Bretonnel Cohen 644

Graph Clustering System for Text-Based Records in a Clinical Pathway
Takanori Yamashita, Naoya Onimura, Hidehisa Soejima, Naoki Nakashima and Sachio Hirokawa 649

Research on Ratio of Dosage of Drugs in Traditional Chinese Prescriptions by Data Mining
Xing-wen Yu, Qing-yue Gong, Kong-fa Hu, Wen-jing Mao and Wei-ming Zhang 653

Retraining Concept Vector Representations of Medical Concepts to Improve Estimates of Semantic Similarity and Relatedness
Zhiguo Yu, Byron C. Wallace, Todd Johnson and Trevor Cohen 657

“Hybrid Topics” – Facilitating the Interpretation of Topics Through the Addition of MeSH Descriptors to Bags of Words
Zhiguo Yu, Thang Nguyen, Ferdinand Dhombres, Todd Johnson and Olivier Bodenreider 662

Identifying Biomarkers of Hepatocellular Carcinoma Based on Gene Co-Expression Network from High-Throughput Data
Ying Zhang, Zhiping Liu and Jing-song Li 667

An Interactive Platform to Visualize Data-Driven Clinical Pathways for the Management of Multiple Chronic Conditions
Yiye Zhang and Rema Padman 672

Part 2

III. Human, Organizational, and Social Aspects

Developing Digital Health and Welfare Services in an International Multidisciplinary Student Team
Outi Ahonen, Elina Rajalaiti, Jonas Tana, Gun-Britt Lejonsvist, Ulla-Mari Kinnunen and Kaija Saranto 679

A User-Centered Glucose-Insulin Data Display for the Inpatient Setting
Michael E. Bowen, Umme Rumana, Ethan A. Killgore and Yang Gong 684

Lack of Training for a Downtime Procedure: End User’s Perceptions of an Electronic Health Record Contingency Plan
Rodrigo Cano, Brenda Bejarano, Mercedes Vidal, Daniel Luna and Sonia Benítez 689

Chile’s National Center for Health Information Systems: A Public-Private Partnership to Foster Health Care Information Interoperability
Daniel Capurro, Aisen Echeverry, Rosa Figueroa, Sergio Guiñez, Carla Taramasco, César Galindo, Angélica Avendaño, Alejandra García and Steffen Härter 693

A Combined Collaborative Information Behaviour (CIB) and Continuity of Care Framework for Modeling Complexity in Colorectal Cancer Screening Access
Caitlin Champion, Ewan Affleck, Gonzalo G. Alvarez and Craig Kuziemsky 696

Clinical Decision Support and Primary Care Acceptance of Genomic Medicine
Dian A. Chase, Sherry Baron and Joan S. Ash 700

An Experimental Comparison of Quality Models for Health Data De-Identification
Johanna Eicher, Klaus A. Kuhn and Fabian Prasser 704

Evaluation of the Association Between Different Patient Indexing Strategies and Effective Indexing in Health Centers of the Public System of the Autonomous City of Buenos Aires: An Exploratory Study
Santiago Esteban, Cecilia Palermo, Leandro Alassia, M. Victoria Giussi, Analía Baum and Fornán González Bernaldo de Quirós 709

Design and Construction for Community Health Service Precision Fund Appropriation System Based on Performance Management
Xing Gao, Yao He and Hongpu Hu 714
Ethical Issues in Implementing National-Level Health Data Warehouses in Developing Countries
Milka B. Gesicho, Troy D. Moon, Elizabeth Heitman and Martin C. Were

Patients’ Online Access to Electronic Health Records: Current Status and Experiences from the Implementation in Sweden
Maria Hägglund and Isabella Scandurra

What Do They Mean by “Health Informatics”? Health Informations Posts Compared to Program Standards
Josette F. Jones, Enming Zhang, Anand Kulanthaivel and Shilpa Katta

Design of a User-Centered Voluntary Reporting System for Patient Safety Events
Hong Kang and Yang Gong

OpenClinic GA Open Source Hospital Information System Enabled Universal Health Coverage Monitoring and Evaluation in Burundian Hospitals
Gustave Karara, Frank Verbeke, Evelyne Ndabanime, Etienne Mugisho and Marc Nyssen

User Centred Design and Nosocomials in Surgical ICUs: A Mobile Application for Peer Monitoring and Training in Hand Hygiene
Nadish Kariyawasam, Ming Chao Wong and Paul Turner

An Experimental Comparison of a Co-Design Visualizing Personal Drug Information and Patient Information Leaflets: Usability Aspects
Souadbeh Khodambashi, Dagrunn Haugland, Anette Ellingsberg, Hanne Kottum, Janne Kutschera Sund and Øystein Nyтро

Mutual Learning and Exchange of Health Informatics Experiences from Around the World – Evaluation of a Massive Open Online Course in eHealth
Sabine Koch and Maria Hägglund

50th Anniversary International Medical Informatics Association (IMIA) History Working Group and Its Projects
Casimir A. Kulikowski, George Mihalas, Robert Greenes, Valerio Yacubsohn and Hyeoun-Ae Park

Towards a Usability and Error “Safety Net”: A Multi-Phased Multi-Method Approach to Ensuring System Usability and Safety
Andre Kushniruk, Yalini Senathirajah and Elizabeth Borycki

The New HIT: Human Health Information Technology
Tiffany J. Leung, Mary K. Goldstein, Mark A. Musen, Ruth Cronkite, Jonathan H. Chen, Assaf Gottlieb and Eran Leitersdorf

Global eHealth, Social Business and Citizen Engagement: A Natural Convergence?
Siaw-Teng Liew, Alvin Marcelo, Padmanesan Narasimhan, Md. Mahfuz Ashraf and Pradeep Ray

P-Care BPJS Acceptance Model in Primary Health Centers
Hosizah Markam

The Australian Health Informatics Competencies Framework and Its Role in the Certified Health Informatician Australasia (CHIA) Program
Fernando Martin-Sanchez, David Rowlands, Louise Schaper and David Hansen

Information and Communication Gaps in Intersectoral Healthcare Processes for Dementia Patients
Bianca Oppermann, Bettina Zippel-Schultz, Uta Augustin, Andrea Popa, Carsten Schultz and Reinhold Haux

Equality Challenges in the Use of eHealth: Selected Results from a Danish Citizens Survey
Lone Stub Petersen and Pernille Bertelsen

Analysis of the Updated Swedish Regulatory Framework of the Patient Accessible Electronic Health Record in Relation to Usage Experience
Isabella Scandurra, Maria Pettersson, Benny Eklund and Leif Lyttkens

Green Turning Brown – Domain Engineering for Social and Health Services in Finland
Reima Suomi, Pirkko Nykänen, Tapio Vepsäläinen and Riina Hiltunen

Toward Automatic Reporting of Infectious Diseases
Hsiao-Mei Tsao, Chi-Ming Chang, Jen-Hsiang Chuang, Ding-Ping Liu, Mei-Lien Pan and Da-Wei Wang

Change Management Strategies: Transforming a Difficult Implementation into a Successful One
Maria Victoria Giassi, Analia Baum, Fernando Plazzotta, Pablo Maguerza and Fernán González Bernaldo de Quirós
Evaluate the Usability of the Mobile Instant Messaging Software in the Elderly
Tzu-Ning Wen, Po-Liang Cheng and Po-Lun Chang

Augmented Reality in Nursing: Designing a Framework for a Technology Assessment
Hanna Willer, Marcus Garthaus and Hartmut Remmers

Design a Learning-Oriented Fall Event Reporting System Based on Kirkpatrick Model
Sicheng Zhou, Hong Kang and Yang Gong

IV. Knowledge Management

Managing User Needs During the EHR Implementation in Buenos Aires City: The HelpDesk Role
L. Allassia, C. Palermo, F. Recondo, M. Giussi, A. Stieben, A. Baum and F. Gonzalez Bernaldo de Quirós

Expressing Biomedical Ontologies in Natural Language for Expert Evaluation
Muhammad Amith, Frank J. Manion, Marcelline R. Harris, Yaoyun Zhang, Hua Xu and Cui Tao

Eliciting the Intension of Drug Value Sets – Principles and Quality Assurance Applications
Nathan J. Bahr, Scott D. Nelson, Rainer Winnenburg and Olivier Bodenreder

Comparison of Three English-to-Dutch Machine Translations of SNOMED CT Procedures
Ronald Cornet, Carly Hill and Nicolette de Keizer

Trends in Fetal Medicine: A 10-Year Bibliometric Analysis of Prenatal Diagnosis
Ferdinand Dhombres and Olivier Bodenreder

The Portal of Medical Data Models: Where Have We Been and Where Are We Going?
Sophia Geßner, Philipp Neuhaus, Julian Varghese, Philipp Bruland, Alexandra Meidt, Iñaki Soto-Rey, Michael Storck, Justin Doods and Martin Dugas

Perceiving the Usefulness of the National Cancer Institute Metathesaurus for Enriching NCIt with Topological Patterns
Zhe He, Yan Chen and James Geller

Shiny FHIR: An Integrated Framework Leveraging Shiny R and HL7 FHIR to Empower Standards-Based Clinical Data Applications
Na Hong, Naresh Prodduturi, Chen Wang and Guoqian Jiang

Key Relation Extraction from Biomedical Publications
Lan Huang, Ye Wang, Leiguang Gong, Casimir Kulikowski and Tian Bai

Knowledge Management in Health Technology SMEs
Juhamatti Huusko, Sirpa Kuusisto-Niemi and Kaija Saranto

Effects of Implementing a Tree Model of Diagnosis into a Bayesian Diagnostic Inference System
Satoshi Iwai, Yoshimasa Kawazoe, Takeshi Imai and Kazuhiko Ohe

A Consensus-Based Approach for Harmonizing the OHDSI Common Data Model with HL7 FHIR
Guoqian Jiang, Richard C. Kiefer, Deepak K. Sharma, Eric Prud’hommeaux and Harold R. Solbrig

Text Data Mining of Aged Care Accreditation Reports to Identify Risk Factors in Medication Management in Australian Residential Aged Care Homes
Tao Jiang, Siyu Qian, David Hailey, Jun Ma and Ping Yu

An Ontology-Based Approach to Estimate the Frequency of Rare Diseases in Narrative-Text Radiology Reports
Charles E. Kahn Jr.

On Incentives for Open Access Publishing: A Survey at IMIA’s Annual General Assembly During HEC2016
Stefanie Kuballa, Mareike Schulze, Corinna Mielke, Olaf Gefeller and Reinhold Haux

Peer Review of Clinical Information Models: A Web 2.0 Crowdsourced Approach
Heather Leslie and Stijep Ljosand Bakke

A Semi-Automatic Framework to Identify Abnormal States in EHR Narratives
Xiaojuan Ma, Takeshi Imai, Emiko Shinohara, Ryota Sakurai, Koji Kozaki and Kazuhiko Ohe

Application of Ontology Technology in Health Statistic Data Analysis
Minjiang Guo, Hongpu Hu and Xingyun Lei
V. Quality and Safety, and Patient Outcomes

An Innovative Approach to Jointly Scheduling and Assigning a Consultation Time to Patients Arriving in the Emergency Department
Faten Ajmi, Sarah Ben Othman, Hayfa Zgaya, Slim Hammadi and Jean-Marie Renard

Design of a Mobile Application for Transfusion Medicine
M.A. Albornoz, S. Márquez, L. Rubin and D. Luna

Assessing Provider-Generated Free-Text Quality in EHR-Integrated Handoff Notes
Elliot G. Arsoniadis, Steven J. Skube, Treva M. Bjerke, Bryan Jarabek and Genevieve B. Melton

Accessing Reliable Health Information on the Web: A Review of the HON Approach
Célia Boyer, Arnaud Gaudinat, Allan Hanbury, Ron D. Appel, Marion J. Ball, Michel Carpentier, Jan H. van Bemmelen, Jean-Paul Bergmans, Denis Hochstrasser, Donald Lindberg, Randolph Miller, Jean-Claude Peterschmitt, Charles Safran, Michèle Thomet and Antoine Geissbühler

Arden Syntax Clinical Foundation Framework for Event Monitoring in Intensive Care Units: Report on a Pilot Study
Jeroen S. de Bruin, Julia Zeckl, Katharina Adlassnig, Alexander Blacky, Walter Koller, Andrea Rappelsberger and Klaus-Peter Adlassnig
Design of an Intelligent Nursing Clinical Pathway and Nursing Order Support System for Traditional Chinese Medicine
   Bao-Fen Ding, Polun Chang, Ping Wang, Hai-Ting Li and Ming-Chuan Kuo 1014

Predicting Length of Stay for Obstetric Patients via Electronic Medical Records
   Cheng Gao, Abel N. Kho, Catherine Ivory, Sarah Osmundson, Bradley A. Malin and You Chen 1019

Group-Based Trajectory Analysis for Long-Term Use of Warfarin Therapy in Atrial Fibrillation Patients
   Shijing Guo, Xiang Li, Xin Du, Haifeng Liu and Guotong Xie 1024

CTdBem – A New Protocol for Ultra Low Radiation Dose MDCT
   Carlos Jesús Pereira Haygert, Marcos Cordeiro d’Ornellas, Daniel Welfer, Rubens Martins Bastos and Gustavo Nogara Dotto 1029

Successful System, Incomplete Data: Caveats in Reusing Activity Data from Emergency Department Whiteboards
   Morten Hertzum 1033

Improving Patient Safety Through the Design and Development of a Computerized Provider Order Entry for Parenteral Nutrition Linked to a Barcode Medication Administration Record
   Oscar I. Jáuregui, Lucila Bruchanski, Daniel A. Rizzato Lede, Carlos M. Otero and Daniel R. Luna 1038

Use of EHR Data to Identify Factors Affecting the Time to Fall
   Hyesil Jung and Hyeoum-Ae Park 1043

Identifying and Synchronizing Health Information Technology (HIT) Events from FDA Medical Device Reports
   Hong Kang, Frank Wang, Sicheng Zhou, Qi Miao and Yang Gong 1048

Comparative Performance Analysis of Different Fingerprint Biometric Scanners for Patient Matching
   Noah Kastiti, Judy Wawira, Saptarshi Purkayastha and Martin C. Were 1053

Development and Evaluation of a Blood Glucose Management System for Reducing the Delay in Measurement
   Teramoto Kei, Okara Tsuyoshi, Koshitani Rie, Takahiro Murata, Yoriyuki Yoko, Hotta Erika, Endo Yusuke, Ueki Masaru and Kondoh Hiroshi 1058

Evaluation of a Decision Support System for Laboratory Service Patients
   Georgy Kopanitsa 1063

Effective Usability Engineering in Healthcare: A Vision of Usable and Safer Healthcare IT
   Andre Kushniruk, Yalini Senathirajah and Elizabeth Borycki 1066

Automated Classification of Multi-Labeled Patient Safety Reports: A Shift from Quantity to Quality Measure
   Chen Liang and Yang Gong 1070

Predicting Harm Scores from Patient Safety Event Reports
   Chen Liang and Yang Gong 1075

The Value of Data and the Value of Questions: Achieving Improvement in Hospital Pharmacy and Medication Safety
   Valentina Lichtner and Tony Cornford 1080

User-Centered Design Improves the Usability of Drug-Drug Interaction Alerts: A Validation Study in the Real Scenario
   Daniel R. Luna, Daniel A. Rizzato Lede, Luciana Rubin, Carlos M. Otero, Juan M. Ortiz, Mónica G. García, Romina P. Rapisarda, Marcelo R. Risk and Fernández González Bernaldo de Quirós 1085

Extracting Follow-Up Recommendations and Associated Anatomy from Radiology Reports
   Thushitha Mabotuwana, Christopher S. Hall, Sandeep Dalal, Joel Tieder and Martin L. Gum 1090

BarCode Medication Administration in ICU: Learning from Our Nurses
   Thelma Maydana, Liliana Giraldo, Zulma González, Bibiana Schachner, John Mayan, Daniel Luna and Sonia Benitez 1095

Procedure for Reconstruction of a Predictive Score of Severe Deterioration in Inpatients
   Hernán Navas and Elián Bourdin 1099

Framework of Performance Measures for Health Information Exchange (HIE)
   Okada Mihoko, Ishida Haku, Watanabe Sunao and Shiratori Yoshimune 1103
A Comparison of Two Principal Systems for Monitoring of Technology-Induced Errors in Electronic Health Records
Sari Palojoki, Elizabeth M. Borycki, Andre W. Kushniruk and Kaija Saranto

Factors Affecting the Time to Occurrence of Hospital-Acquired Pressure Ulcers Using EHR Data
Seul Ki Park and Hyeouen-Ae Park

Precision of EMR Data: The Case for a Drug and Alcohol Service
Siyu Qian, Esther Munyisia, Ping Yu, David Hailey and David Reid

Adverse Drug Event Monitoring with Clinical and Laboratory Data Using Arden Syntax
Andrea Rappelsberger, Klaus-Peter Adlasmig, Jeroen S. de Bruin, Manuela Plössnig, Jochen Schuler and Christina Hofer-Düückelmann

Usability Evaluation of an EHR’s Clinical Notes Interface from the Perspective of Attending and Resident Physicians: An Exploratory Study
Rubina F. Rizvi, Jemna L. Marquard, Marcus A. Seywerd, Terrence J. Adam, Jed T. Elison, Gretchen M. Hultman, Kathleen A. Harder and Genevieve B. Melton

Strengthening Data Confidentiality and Integrity Protection in the Context of a Multi-Centric Information System Dedicated to Autism Spectrum Disorder
Mohamed Ben Said, Laurence Robel, Bernard Golse and Jean Philippe Jais

Mapping the Electronic Health Record: A Method to Study Display Fragmentation
Yalini Senathirajah, Jinglu Wang, Elizabeth Borycki and Andre Kushniruk

Strengthen Cancer Surveillance in Sri Lanka by Implementing Cancer Registry Informatics to Enhance Cancer Registry Data Accuracy, Completeness, and Timeliness
Kamal Seneviratne, Sudath Samaraweera, Eshani Fernando, Suraj Perera and Asanga Hemarathna

Using Therapeutic Circles to Visualize Guideline-Based Therapeutic Recommendations for Patients with Multiple Chronic Conditions: A Case Study with GO-DSS on Hypertension, Type 2 Diabetes, and Dyslipidemia
Brigitte Sérourissi, Alexandre Galopin, Mouhssin Gaounar, Suzanne Pereira and Jacques Bouaud

Development of a Service-Oriented Sharable Clinical Decision Support System Based on Ontology for Chronic Disease
Yong Shang, Yu Wang, Ling Gou, Chengkai Wu, Tianshu Zhou and Jing-song Li

The Paradox of Higher Charges for Lower-Risk Inpatient Admissions: When Healthier Patients Cost More
Lincoln Sheets, Kayson Littile, Lori L. Popejoy and Jerry C. Parker

A Design of a Surgical Site Verification System
Biyu Shen, Yan He and Haoyang Chen

Characterizing Restorative Dental Treatments of Sjögren’s Syndrome Patients Using Electronic Dental Records Data
Zasim Siddiqui, Yue Wang, Payal Makkad and Thanaka Thyvalikakath

Analysis of Clinical Variations in Asthma Care Documented in Electronic Health Records Between Staff and Resident Physicians
Sungkwan Sohn, Chung-Il Wi, Young J. Juhn and Hongfang Liu

Medical Effect of Venous Thromboembolism Prophylaxis Systems and Common Input Categories: Preliminary Findings from a Systematic Review
Julian Varghese, Maren Kleine, Sophia Isabella Gessner, Sarah Sandmann and Martin Dugas

CD-KES: An Ontology Based Knowledge Education System for Patients with Chronic Diseases and Its Constructing Approach
Chengkai Wu, Ling Gou, Yu Wang, Yong Shang, Yu Tian and Jing-song Li

Gathering Real World Evidence with Cluster Analysis for Clinical Decision Support
Eryu Xia, Haifeng Liu, Jing Li, Jing Mei, Xiejun Li, Enliang Xu, Xiang Li, Gang Hu, Guotong Xie and Meiling Xu

Context-Sensitive Clinical Alert Packages Written in Arden Syntax
Julia Zeckl, Katharina Adlasmig, Renate Fossler, Alexander Blacky, Jeroen S. de Bruin, Walter Koller, Andrea Rappelsberger and Klaus-Peter Adlasmig
Validation of the Chinese Version of the Functional Oral Intake Scale (FOIS) Score in the Assessment of Acute Stroke Patients with Dysphagia
Hongzhen Zhou, Yafang Zhu and Xiaomei Zhang

The Impact of Censoring Drug Switching in Medication Adherence Measures of Chronic Single Ingredient Oral Drugs
Vivienne J. Zhu, J. Marc Overhage, Qianli Ma and Patrick B. Ryan

Multimodal e-Health Services for Smoking Cessation and Public Health: The SmokeFreeBrain Project Approach

Panagiotis D. Bamidis, Evangelos Paraskevopoulos, Evdokimos Konstantinidis, Dimitris Spachos, Antonis Billis

Lab of Medical Physics, Medical School, Aristotle University of Thessaloniki, Greece

Abstract

Smoking is the largest avoidable cause of preventable morbidity worldwide. It causes most of the cases of lung cancer and chronic obstructive pulmonary disease (COPD) and contributes to the development of other lung diseases. SmokeFreeBrain aims to address the effectiveness of a multi-level variety of interventions aiming at smoking cessation in high risk target groups within High Middle Income Countries (HMIC) such as unemployed young adults, COPD and asthma patients, and within the general population in Low-Middle Income Countries (LMIC). The project addresses existing approaches aimed to prevent lung diseases caused by tobacco while developing new treatments and evaluating: (i) Public Service Announcement (PSA) against smoking, (ii) the use of electronic cigarettes, (iii) neurofeedback protocols against smoking addiction, (iv) a specifically developed intervention protocol based on behavioral therapy, social media/mobile apps and short text messages (sms) and (v) pharmacologic interventions. Emphasis in this paper, however, is placed on the e-health, m-health, open (big) data, mobile game and neuroscientific challenges and developments upon facilitating the aforementioned interventions.

Keywords:

Smoking Cessation, Telemedicine, Neuroscience

Introduction

Smoking is the largest avoidable cause of preventable morbidity and premature mortality worldwide [1]. The prevalence of smoking worldwide is estimated at about one billion smokers, half of whom will die prematurely as a consequence of their addiction, unless they quit [2]. Smoking causes approximately 85% of the cases of lung cancer and chronic obstructive pulmonary disease (COPD) and contributes to the development of many other lung diseases [3]. Therefore, the control of smoking and the active reduction of exposure to tobacco substances in the environment are considered highly important interventions for lung disease prevention [4].

According to World Health Organization (WHO) one third of the world adult population today, 1.1 billion people are smokers and 3.5 million deaths per year are attributed to smoking. It is estimated that in 2020 the number of deaths per year will be increased to 10 million. Smokers are 13 times more likely to die from COPD than nonsmokers.

Tobacco consumption is highly influenced by socioeconomic factors, affecting mostly low- and middle-income countries as well as vulnerable populations within high income countries. Additionally, smoking causes health inequality between gender and age groups [4], while it significantly elevates the preventable morbidity and premature mortality rates worldwide.

In the past, our team has described an approach towards the development of an integrated system supporting the smoking cessation network initiatives in Greek public hospitals. The system combined the availability of an open source, web based EHR subsystems, with a Web 2.0 facilitated e-learning component for supporting continuing medical education and promoting public awareness [5].

With these in mind, the SmokeFreeBrain project (www.smokefreebrain.eu), funded by the H2020 programme of the European Commission, aims to address the effectiveness of a multi-level variety of intervention strategies for smoking cessation in high risk target groups within High Middle Income Countries (HMIC) such as unemployed young adults, chronic obstructive pulmonary disease (COPD) and asthma patients, and within the general population in Low Middle Income Countries (LMIC). As the main effect of the recent economic crisis in various European countries, is a significant increase of youth unemployment. The present project focuses on how this socioeconomic development affects the vulnerability of the young population. The project addresses existing approaches aimed to prevent and control lung diseases caused by tobacco consumption, while proposing the development of new treatments and analyzing their contextual adaptability to the local and global health care system as it is affected by the recent socioeconomic changes [6].

In this paper, the various SmokeFreeBrain interventions are first outlined. Emphasis is then placed on the facilitation of these interventions with various e-health, m-health, open (big) data, mobile game and neuroscientific developments where technical aspects such as the design and system architectures of the database registry, as well as, the mhealth systems, together with the informatics implications for pilot preparations are discussed.

SmokeFreeBrain Objectives and Concept

The objectives of the project are outlined below:

- Examine the effects of the use of electronic cigarettes during the initial phase of smoking cessation along with the possible formation of carcinogenic nitrosocompounds via the exposure to nicotine through electronic cigarette vaping.
- Examine the global DNA methylation status under two different situations, tobacco smoking and inhaling e-cigarette vapor.
- Development and evaluation of a novel neurofeedback protocol for smoking cessation.
- Develop a smoking cessation intervention based on adherence to physical activity with ICT support (App Gamification, Facebook and SMS).
- Generate and validate a set of software tools that can be used to inform EU policymakers and local governments as to how to produce optimal Public Service Announcements (PSA) regarding smoking.
- Develop a best practice guide for promoting smoking cessation and how these can be applied in large scale.
- Evaluate and report on the effectiveness of the proposed interventions in terms of cost, socioeconomic and health demographics terms and report to policy making bodies.

SmokeFreeBrain follows an interdisciplinary approach in various relevant fields in order to generate new knowledge. State of the art techniques in toxicology, pulmonary medicine, neuroscience and behavior are utilized to evaluate the effectiveness of: (i) Public Service Announcement (PSA) against smoking, (ii) the use of electronic cigarettes with and without nicotine as a harm reduction approach and/or cessation aid, (iii) a specifically developed neurofeedback intervention protocol against smoking addiction, (iv) a specifically developed intervention protocol based on behavioral therapy, social media/mobile apps and short text messages (sms) and (v) pharmacologic interventions.

In attempting to set a summarised outline of the project in a nutshell, one may say that it will use samples of the populations showing high vulnerability to smoking in order to study the effects of five distinct interventions for smoking cessation to measure their cost-effectiveness and allow conclusions regarding the outcomes scalability in terms of health economics. Figure 1 illustrates this concept.

SmokeFreeBrain Interventions

**e-Cigarette Intervention**

Electronic cigarettes (EC) are a product that can be used for consumption of nicotine-containing vapour via a mouth piece, or any component of that product, including a cartridge, a tank and the device without cartridge or tank. Electronic cigarettes can be disposable or refillable by means of a refill container and a tank, or rechargeable with single use cartridges. ECs or electronic nicotine delivery systems (ENDS) are also defined as devices whose function is to vaporize and deliver to the lungs of the user a chemical mixture typically composed of nicotine, propylene glycol and other chemicals, although some products claim to contain no nicotine. These products are not currently regulated or monitored. As such, contents may vary and may not be known to the consumer. The safety of ECs has not yet been scientifically demonstrated. Additionally the products vary widely in the amount of nicotine and other chemicals they deliver and there is no way for consumers to find out what is actually delivered by the product they have purchased. Consumers often believe that the use of ECs is safer than smoking tobacco. The chemicals used in ECs have not been fully disclosed, and there are no adequate data on their emissions [7].
Public Service Announcements (PSAs)

Governments across the world are required to disseminate information concerning risks to public health and to promote messages that encourage healthier life-style options to improve public health and reduce the huge burden placed on state spending from state subsidized health care in countries with social security systems such as Germany, the UK and France. In this context, PSAs are non-commercial advertisements intended to achieve attitudinal and behavioural changes in the public. PSAs are at the core of many public health campaigns against smoking, and other possible public health problems.

When effective, PSAs are of substantial benefit to public welfare. However, the lack of reliable, quantitative and objective means of evaluating advertising effectiveness is one of the key impediments to better PSA outcomes. In addition, poorly designed PSAs can often have effects that are contrary to their desired goals [11]. Over the past few years, considerable developments in methodologies to record brain activity (e.g. functional Magnetic Resonance Imaging (fMRI), Electro-Encephalography (EEG)) and psychophysics have allowed novel paradigm designs and analyses providing key insight into both the explicit (conscious) and implicit (subconscious) cerebral responses to PSAs. This intervention uses modern neuroscientific tools with the latest thinking and methodological approaches available in the fields of marketing and social science and the interaction of experts from academia, private companies and governmental organizations to derive a new device that can measure and predict the efficacy of PSAs related to smoking abuse.

Pharmacologic interventions

This intervention will investigate the effects of current pharmacological treatments on sleep quality and physiology of COPD and asthma patients as well as in young unemployed adults focusing on two well-known drugs: Varenicline and bupropion. Varenicline is a chemical substance that it used as medication for smoking cessation and affects the nervous system by making nicotine less effective in two different ways: by acting like nicotine as a partial agonist to reduce craving for cigarettes or by replacing nicotine (agonist) and decreases the pleasurable effect of cigarettes. However, there are studies that report an adverse drug reaction of “abnormal sleep related events” associated with varenicline. To allow for such inferences, SmokeFreeBrain will conduct a sleep study, which will be performed using overnight polysomnographic (PSG) recordings consisting of electroencephalography (EEG), electrooculography (EOG), electrocardiography (ECG) and electromyography (EMG) sensors.

The insights gained from the pharmacological studies will generate new knowledge regarding the toxicity of these interventions according to their effectiveness. These effects will then be compared with the toxicity of e-cigarettes via that intervention, allowing inferences regarding the safety of the relevant, corresponding use.

ICT positioning of the project

SmokeFreeBrain will develop and deploy both cutting edge and stable, well-understood, technologies (from previous EU projects and commercial partners) within the new field of smoking cessation support, including neurofeedback intervention, gamification platform, mobile app for delivering challenges and interaction information, serious games promoting physical exercise, neurometric approaches, and decision support for challenging and motivational tasks and smoking related profile databases to maximise value from research and to optimise commercial opportunities. Technical partners have assessed technology readiness levels of existing components to be used in SmokeFreeBrain. Figure 2 illustrates the current technology readiness levels (TRLs) in line with the corresponding estimated readiness level at the end of the project (TRLs vary from 1 to 9).

![Figure 2 – TRLs of SmokeFreeBrain technologies at project start and estimates envisioned at the end of the 3 year run.](image)

Data Management Plan

The data management plan will guide all activities regarding the anonymization, exchange and release of data gathered in the pilot sites as required for participation in the Open Research Data Pilot in H2020. Datasets that are produced within the SmokeFreeBrain project span from smokers’ demographic and clinical data to outcome measures of several clinical interventions and their cost-effectiveness results. These data will allow for the benchmarking of the different approaches when dealing with smoking cessation, providing a common basis for further policy decision making. Since SmokeFreeBrain pilots involve human participants, data collected will contain sensitive personal information. Focus is also given to possible ethical issues and access restrictions regarding personal data so that regulations on sensitive information are not violated.

The data management portal will be based on the popular open source software CKAN and it will be accessible through a portal (endpoint) at the following address: ckan.smokefreebrain.org

CKAN is a powerful data management system that makes data accessible by providing tools to streamline publishing, sharing, finding and using data. CKAN is aimed at data publishers (national and regional governments, companies and organizations) wanting to make their data open and available. The software supports strong integration with third-party CMS’s, such as Drupal and WordPress.

Among the portal’s features will be:

- Complete catalog system with an easy to use web interface and a powerful API
- Integration with the profile database system
- Data visualization and analytics
- Fine access controls
- Raw data and metadata storage
• Search by keyword or filter by tags. See dataset information at a glance.
• Rich application programming interface (API), and over 60 extensions including link checking, comments, and analytics and many more.

The SmokeFreeBrain Profile database

The profile database will be a clinical trial database. It will be a general data hub for the needs of the project and will hold data from all interventions. Partners can be use the profile database with 2 ways:

• As a database for their intervention
• As a hub for storing data from interventions for processing purposes

In the first case, partners will be able to insert their data into the database. In the second case, they have to send the data via web services, which will follow the ISO EN 13606 standard. A general overview of the system architecture can be shown in Figure 3. The profile database will produce reports and statistics based on the stored data. The reports will be use to evaluate the results of the interventions of the project.

The SmokeFreeBrain API

This API is used to Post, Read and Update data in the Profile Database using the CEN/ISO EN13606, a European norm from the European Committee for Standardization (CEN) which is also approved as an international ISO standard [12].

The SmokeFreeBrain SoLoMo App

The main features of the So-Lo-Mo app are:

• Personal profile
• Achievements: Cigarettes not smoked, money savings, hours of live regained, time smoke free
• Total fitness time (Google Fit integration): Daily average, monthly average, days above the average
• Self-help contents
• Motivational tools: Readings, relaxation tool and mini-games
• Relapse tracker
• Encouraging messages: Both from the system, and from/to other users

The SmokeFreeBrain SoLoMo App mini-games

An interesting feature of the So-Lo-Mo app is the concept of mini-games. The relevant contribution of mini-games in smoking cessation has already been recognized in recent studies [13]:

• Playing Tetris decreases craving strength for drugs
• Puzzle-solving games reduce craving for nicotine
• Breath-control App emulating the physiological responses smokers get from smoking
• Crushing virtual cigarettes contributes to smoking cessation

We focused on 3 mini games:

• Crushing cigarettes [14]
• Breathing control by blowing up balloons
• Physical Exercise Coach/Instructor (based on the webFitForAll exer-gaming platform protocol) [15, 16]

For example, in the Blowing up Balloons mini-game, emphasis is placed on breathing control. The user is asked to blow close to the microphone when the balloon is green. If the user blows when the balloon is red, the balloon may pop. If the user does not blow when the balloon is green, the balloon deflates quickly. The number of totally blown balloons in 1 min reflects the total score, while the pop balloons are counted too. This is based on the Jamalian et al. conceptual study:

• Phone app that emulates the physiological responses smokers get from smoking
• Innovative breath-control element, which mimics the physiological and perceived effects of nicotine as well as the relaxant effects of smoking.
• The goal is to give players a cigarette-free, non-invasive way to satisfy their nicotine cravings

Figure 4 provides a rough screenshot of the game interfaces.

Envisioning the SmokeFreeBrain stakeholder ecosystem

The contribution of SmokeFreeBrain towards the creation of a social ecological model relies on understanding the multiple stakeholders and their needs. SmokeFreeBrain will develop and support a collaborative health-ecosystem by bringing together the relevant key stakeholders who will testify on their changing interactions and endorse the implemented interventions to ensure maximum health benefits. At the policy level, alliance with national healthcare policy makers will capitalize efforts and scale up interventions in a global context. The organisational stakeholders are hospitals, health service providers and national authorities who monitor existing approaches to prevention or develop treatments. The community stakeholders include the scientific community (e.g. researchers, academics), commercial actors
(pharmaceutical industry, insurers) and cross-sectoral experts (e.g. researchers on environmental effects). The interpersonal level includes the So-Lo-Mo community, existing smoking cessation networks, family and friends. The patient/smoker is central to the entire ecosystem. SmokeFreeBrain will inform all levels of the framework by providing access to real and valuable information on the establishment of effective interventions for the prevention and treatment of lung diseases. Figure 5 illustrates the above described ecosystem.

![Figure 5– SmokeFreeBrain stakeholder ecosystem.](image)

Conclusion

The SmokeFreeBrain project kicked off in November 2016 and is expected to have a three year duration. At the point of writing this paper, numerous multi-centric trials are underway. These are expected to shape the way forward by providing innovative systems, interventions and new, original, knowledge derived as statistical analysis and economic evaluation will soon kick-off. This paper has attempted to provide some overall, but technically oriented glimpses on the project concept. Given space limitations and the early stages of the trials, more details and results were thought improper for the purposes of this paper. Nevertheless, the technical frontiers which have been outlined in this paper can not be understated.

Using Smartphones for Research Outside Clinical Settings:
How Operating Systems, App Developers, and Users
Determine Geolocation Data Quality in mHealth Studies

Abstract

Smartphones that collect user geolocation provide opportunities for mobile Health (mHealth). Although granularity of geolocation data may be high, data completeness depends on the device’s operating system, application developer decisions, and user actions. We investigate completeness of geolocation data collected via smartphones of 5601 people that self-reported daily chronic pain symptoms on 349,293 days. On 17% of these days, hourly geolocation data is reported, but days with 0 (16%), 1 (14%) and 2 (13%) geolocations are common. Android phones collect geolocation more often than iPhones (median 17 versus 2 times a day). Factors on operating system level and individual user level influence completeness of geolocation data collected with smartphones. mHealth researchers should be aware of these factors when designing their studies. The mHealth research community should devise standards for reporting geolocation data quality, analysing systematic differences in data quality between participant groups, and methods for data imputation.

Keywords:
Mobile Health (mHealth); Smartphone; Longitudinal Studies

Introduction

The high penetration of smartphones in our society enables large-scale collection of self-reported data in real-time for research outside clinical settings. Moreover, these temporarily-rich data sets can be complemented with passively collected data by smartphone sensors, such as physical activity, sleeping patterns or geolocation data [1]. Geolocation data is especially useful as it can be linked to openly available data sets with high spatial and temporal resolution (e.g. climate, weather, air pollution).

Usage of smartphones to collect geolocation data passively has many advantages. It reduces the burden of participation as participants can use their own device and do not need to manually enter location data. It is less prone to recall bias compared to keeping location diaries, increasing the internal validity of studies [2]. Through the Global Positioning System (GPS), location can be sampled both frequently and accurately, rendering assumptions that participants always stay at their home or work postcode unnecessary.

Although granularity of geolocation data may be higher using smartphones, completeness and accuracy of passively collected sensor data may be less when using smartphones rather than clinically-approved devices and more variable between participants who use different smartphones. The accuracy and completeness of geolocation data are affected by a variety of factors relating to operating system [3], application (app) developer decisions [4; 5] and smartphone settings defined by the user [4; 5], which are partially outside researchers’ control. Thus, if geolocation completeness patterns systematically differ between participant groups, the validity of study results may be compromised.

The purpose of this study is to assess completeness of geolocation data collected during the study Cloudy with a Chance of Pain. This is a national UK smartphone study investigating the association between the weather and chronic pain. Study participants rate ten aspects of their daily symptoms in the study’s smartphone app, which collects geolocation data to retrieve hourly weather data from the nearest weather station via the Met Office DataPoint service.

We investigated data completeness for the study population and compared the number of geolocation observations between Android and iPhone users, as well as their demographics.

Sampling geolocation data: location services on Android and iOS smartphones

The availability of geolocation data depends on the smartphone’s operating system, various settings defined by the app developer, and phone settings chosen by the user [4; 5]. The “Cloudy with a Chance of Pain” app was developed for the two operating systems with largest market share in the UK: Android (53% market share), developed by Google and used on many different brands of phones, and iOS (44% market share), developed by Apple for iPhones only. We will first discuss settings that affect availability and accuracy of geolocation data independent of operating system, then discuss the operating system-specific settings under various developers’ decisions and finally the user-defined settings. Choices made during development of the Cloudy with a Chance of Pain app are listed in the Methods section below.

Both operating systems can employ the GPS, network signals (a combination of WiFi and cell-tower signals, and, in some cases, signals of so-called Bluetooth beacons), or both to determine the smartphone user’s geolocation. These strategies
vary in accuracy, availability and battery power consumption. GPS provides the highest accuracy, but only works outside of buildings and uses high battery power. Deriving a user’s location based on network signals usually has a lower accuracy, but consumes less battery power and is available both inside and outside. Battery consumption also depends on frequency of location requests, the requested accuracy and the frequency of uploading location data to the application’s servers. App developer guides for both Android and iOS applications encourage app developers to choose settings that preserve battery power.

In both operating systems, apps can be ‘active’ (in use on the smartphone’s screen), ‘in the background’ (not in use, but not terminated), or ‘not running’ (not launched or terminated by system/user).

**Location services in Android**

For Android, Google’s mobile operating system, app developers specify the logic for receiving location updates: what strategy to use (GPS, network, both), frequency, accuracy and the thresholds for requesting updates (time interval or change in distance). The app collects multiple location updates from the GPS and/or Network Location Provider for a specified amount of time, and then chooses the best estimate. The logic for best estimate is determined by the app developer, depending on the purpose of the app (e.g. most recent, most accurate). Usage of the GPS provider and size of window for collecting location updates are associated with highest power consumption.

In Android, location updates are available when the app is running, when the app is in the background, but not when the app is terminated. If a user ‘restricts background data’, location services (and other functionalities) are suppressed when a user is not connected to WiFi. Retrieval of location updates can automatically be resumed when the device is restarted [4].

**Location services in iOS**

For iOS, Apple’s mobile operating system for iPhones, three strategies for determining user location exist: standard location service (GPS), the significant-change location service (network signals, but only supplied after a developer-specified ‘significant change’ in user’s location) and region monitoring (detects user’s entry and exit into specific regions). App developers specify the strategy, frequency of updates and thresholds for requesting updates.

Compared to Android, iOS highly regulates geolocation requests when the app is in the background. Background processes are always time-restricted, making continuous data collection almost impossible. After an app is terminated, GPS geolocation is not available, but the significant-change location service can restart the app ‘in the background’ every fifteen minutes, reporting location changes as long as the operating system allows. If ‘Background App Refresh’ is disabled by the user, none of the location services are operating system allows. If ‘Background App Refresh’ is disabled by the user, none of the location services are available when the app is not in use. Location updates can also be programmed by the developer to pause under certain conditions (e.g. when the user is unlikely to be moving) [5].

**User actions affecting location services**

The smartphone user can also influence availability of geolocation data. On both operating systems, users can (a) disable location services for all apps in the general settings, (b) deny location services for the specific app, (c) switch off the device, (d) switch the device to a mode that does not allow location services (i.e. airplane mode, or, for Android phones, battery-saving mode), or (e) switch off WiFi/mobile network (only affects geolocation through network signals).

**Methods**

**Participants**

UK residents who experienced pain for at least the preceding 3 months were invited to participate, through charity and patient organisations, and through study publicity on television, radio and in newspapers from January 20th 2016. Further requirements for participation were: Age 17 or over, resident in the UK and owning an Android (Android 3 or later) or iOS smartphone (iOS 8 or later). To enrol in the study, participants downloaded the uMotif Cloudy with a Chance of Pain app, consented to participate and completed a baseline questionnaire.

Ethical approval was obtained in December 2015 from the University of Manchester Research Ethics Committee 4 (ref: ethics/15522).

**Cloudy with a Chance of Pain app**

Every day, participants received a reminder to rate ten aspects of their symptoms in the app on a five-point ordinal scale. They could answer (any of) the ten aspects multiple times a day, for example in case of changing pain. In parallel, the smartphone’s GPS passively recorded geolocation up to hourly, thus ideally recording 24 geolocation observations per day.

A participant-day was defined as a day on which the application collected any data (i.e. symptom rating submitted by the participant, passively recorded geolocation, or both).

We distinguished between participant-days with and without symptom data. Participant-days eligible for the main analysis were those on which a participant rated at least one of the ten symptom aspects; days on which a participant did not record any self-reported data, but the app did collect geolocation, were excluded.

The Android and iPhone app were developed to be as similar as possible in their geolocation retrieval strategy. The app uses both GPS (outdoors) and network signals (inside buildings). Every hour on the hour, it retrieves the last observed geolocation in the previous 60 minutes and its accuracy. If only network signals are available, the location update is only triggered in case of significant change (i.e. if a user is inside a building and does not move for an hour, the event is not fired). Geolocations and their timings are saved by the app until participants have internet connection, and then sent to the servers.

**Analysis**

Participants eligible for this analysis were those recruited between 20 January and 16 November 2016 and who had provided symptom data for at least 7 separate days.

We analysed data completeness for all participant-days that met the inclusion criteria. We compared data completeness between Android and iOS participant-days, and the demographic characteristics between the Android and iOS users. The Mann–Whitney U test was used to test whether the number of geolocations per participant-day differed between operating systems and whether the number of symptoms per participant-day differed between operating systems.
Results

Subjects

Figure 1 shows the flowchart of study participants. A total of 12,441 people downloaded the smartphone application. We excluded participants who did not provide any symptom data at all ($N = 1222$), that provided symptom data for less than 7 days ($N = 5383$) or for whom we could infer that they manually disabled location services for our app, never allowing geolocation requests ($N = 205$). Of the 5601 remaining participants, 47% used an Android device, 17% used an iOS device and for 37% the device type could not be determined because the users enrolled in the study before reporting of operating-system type was added to the app’s functionalities.

Figure 1 – Flowchart of number of participants. We excluded participants who never submitted symptom data, symptom data on less than 7 days or that did not give allow geolocation requests.

Participant-days

Figure 2 shows the participant-days. The 5601 included participants provided data on 492,080 days. We excluded participant-days that did not provide any symptom data, a total of 349,293 days. Of the 349,293 participant-days, 28% were provided by the iOS users, 46% were provided by the Android users and 26% were provided by users for which operating system was unknown. On average, participants submitted symptom data on 62 days. The median number of days was 33 (IQR: 14–76).

Figure 2 – Participant-days of the 5601 included participants.

Overall completeness of geolocation data

Figure 3 shows the distribution of completeness of geolocation data for days on which users submitted symptom data. Of all participant-days, 16% had no geolocation data. Of the remainder, the most common number of geolocations was 24 (17%), followed by 1 (14%), then 2 (13%). Figure 4 shows the distribution of geolocation data completeness by known device type for all days of participants, as percentage of participant-days per device type. Most of the 101,714 participant-days collected by iOS devices collected either two geolocations (27%) or one geolocation (26%). For the 163,983 participant-days collected by Android devices, the most common were 24 geolocations (32%), followed by zero geolocations (18%). Table 1 shows that the median number of GPS observations was 17 for Android participant-days and 2.8 for iOS participant-days. The Mann–Whitney $U$ test showed a statistically significant difference in distribution of number of geolocations per participant-day.
between both operating systems ($p < 0.01$). However, the difference in number of symptoms submitted by the participants (mean 10.4 versus 10.3) is not practically meaningful. This difference suggests that an average Android user submits one complete symptom rating more than an iOS user after 100 days of symptom data entry. The statistically significant difference in symptom ratings between the two operating systems can be explained simply by the large volume of data.

### Table 1 – Summary of data completeness of geolocation and self-reported data completeness per participant-day for Android and iOS users. Number of symptom data entries per participant-day refers to the number of symptom aspects rated by that participant (one complete submission consists of 10 symptom aspects).

### Discussion

We investigated data completeness of a large mobile Health (mHealth) study in which participants rated ten aspects of their chronic pain in a smartphone app that simultaneously collected their geolocation. Although the app was developed to retrieve 24 geolocations per day (i.e. hourly), it was only successful on 17.3% of the participant-days. Part of the missing data can be explained by users switching to airplane mode or battery-saving mode during the day. Users may also have manually terminated the app, in which case geolocation updates are only triggered in case of ‘significant change’. Participants are unlikely to make these significant location changes when they are sleeping, and, when they are at work for those with sedentary jobs. Another possible explanation is the timing of the prompt to submit symptoms – 18:24 in the evening – which was expected to fit best into participants’ lifestyles. If participants manually terminate the app and then stay put for the evening, the location strategies not requiring ‘significant change’ would only be launched after 18:24 in the evening, resulting in missing data in the hours before.

Especially interesting is the high prevalence of days with no geolocation updates. Following the app-developers’ settings, we would expect at least one geolocation would be retrieved when the participant submitted symptom data, even if the device had not ‘significantly changed location’ before that time. As many people charge their phones overnight, battery life is expected to decrease over the day, increasing the chance that the phone is in battery-saving mode at 18:24.

Distribution of data completeness differed greatly between the two operating systems. Specifically, an average of 14.1 geolocations was collected on participant-days of Android users, compared to 2.8 for iOS participant-days. As there was no meaningful difference in symptom-entry behaviour between Android and iOS participants, this difference is probably due to the tendency of iOS to block data processing when an app is ‘in the background’. Although percentages of iOS participant-days with few (1–9) geolocation retrievals were higher, a higher percentage of Android participant-days had 0 geolocation retrievals. This may be because historically, only Android phones had a battery-saving mode. This functionality was only introduced in iOS version 9, briefly before the start of this study (16 September 2015), but cannot be installed on the iPhone 4 and older models.

A limitation of this study was that we had to exclude 2047 participants whose operating system was unknown because they joined the study before the functionality of recognising device type was added to the app. Furthermore, we could not determine the cause of missing geolocation data because our application does not collect information on app status or any user-defined settings.

We have not found mHealth studies that are comparable to Cloudy with a Chance of Pain in number of participants, operating system, and geolocation sampling frequency. The most similar study was a feasibility study of using smartphones to investigate air-pollution exposure [7]. This study had a smaller sample size ($N = 54$) and only developed an application for Android phones. They did not use Android’s positioning system, but used external software called Skyhook to collect geolocation more frequently (every 5 minutes). Their study lasted for three months. Due to differences in reporting, it is hard to compare our study with theirs. For example, they excluded 10 participants that did not keep manual location diaries and 4 participants who did not report having their phone powered on 24 hours a day from the analysis. Of the remaining 38 participants, 4 participants had, on average, complete geolocation data (mean number of geolocations per day 288, every 5 minutes) and another 26 participants had an average of 144 or more (i.e. geolocation every 10 minutes). Only one participant had a daily average under 72 data points, probably still providing more granular data than participants in our study. The authors found that geolocation data completeness depended on smartphone manufacturer, mobile network and the time of day data points were collected, as well as whether the user switched the device off or to airplane mode.

Although data completeness of smartphone-collected geolocation may be suboptimal in our study, various strategies may enable mHealth researchers to still perform the intended investigation. Investigating the richer Android geolocation data to infer information on the sparser iOS data might be possible. By analysing individual patterns in geolocation, recurring periods in which no significant change in location takes place may be identified.

The results of as [7] indicate, however, that even when developing an app for Android users only, data completeness may not be optimal. As iOS’s market share is 44% in the UK (large, compared to Brazil’s 4% and China’s 17% [6]), including both Android users and iOS users in medical studies, may reduce selection bias. On the other hand, any systematic differences between iOS users with sparse geolocation data and Android users with richer geolocation data could also compromise the study’s validity.

In conclusion, this study shows that mHealth researchers collecting geolocation via participants’ own smartphones may still encounter missing data, especially in participants that use iPhones rather than Android devices. As future work we plan to investigate robust methods for imputing geolocation data. Researchers should develop research smartphone applications with the operating systems’ specifications in mind and instruct participants to refrain from configuring their phone to settings that do not allow geolocation requests. In addition, the mHealth research community should devise standards for reporting geolocation data quality and analysing systematic differences between participant groups.
Conclusion

We have shown that a smartphone app, when sampling the user’s geolocation at regular intervals, does not always collect hourly geolocation. Missing data is more common in iPhone users compared to Android users.

To increase the data quality of geolocation data, mHealth researchers should be conscious that geolocation availability and accuracy depends upon the operating system, app developer and user. Smartphone applications should be designed with these factors in mind.

Our results indicate that geolocation sampling may also be suppressed by the operating system, especially on iOS devices, leading to missing data outside of researchers’ control. Methodologies to assess – and possibly correct for – systematic differences in data quality between groups of participants should, therefore, be devised.

The Future of Mobile Usability, Workflow and Safety Testing

Abstract
In this paper, the authors outline a vision for the future of mobile usability, workflow and safety testing. The authors argue for the use of glasses that can audio and video record usability, workflow and safety data. Here, citizens, patients and health professionals would become collectors of study data as they use mobile devices and software to support healthcare in the real world. This has become quite feasible with the introduction of low-cost glasses and software applications that allow for the uploading of data for additional analysis by researchers and evaluators of mobile technologies.

Keywords:
Patient Safety; Health Information Systems; Medical Errors

Introduction
Mobile healthcare is on the rise. Citizens and health professionals are using mobile phones to support their healthcare anytime and anywhere (i.e. in the hospital, home and community) [1]. Yet, the usability, safety and workflow implications of these devices and their associated software applications has not been fully researched [2-4]. In this vision paper we consider the use of glasses that audio and video record in terms of: (1) usability, workflow and safety testing, (2) citizens as collectors of audio and video data for research, (3) the potential of video and audio recording devices, (4) the methodological issues associated with using glasses that audio and video record, and (5) future research directions.

Background Literature Review

Why is Usability, Workflow and Safety Testing of Mobile Devices and their Software Important?

Around the world, citizens (e.g. patients, caregivers and health professionals) are using mobile devices such as tablets, mobile phones and smart watches to support their health and wellness, as well as to engage in activities related to healthcare (e.g. looking up health research online, recording physiologic data, using mobile software applications) [1]; for example, using mobile healthcare software applications (e.g. exercise, diet and mood monitoring applications) to self-manage their wellness and chronic diseases [1]. This is consistent with Fox and Duggan’s research findings that identify 38% of American adults use exercise, fitness, pedometer or heart rate monitoring health applications; 31% use diet, food or calorie counter software applications; and 12% use mobile weight monitoring software applications [5].

In addition to this, citizens are repurposing existing mobile technologies (e.g. text messaging, mobile calling, photo applications), and using social media software applications that are not traditionally thought of as healthcare applications (e.g. Twitter®, Facebook®, YouTube®) to obtain and communicate health and healthcare information and to manage their health (e.g. take a picture of a rash) and during health crises (i.e. to communicate information about a family member who is critically ill) [1,5].

Internationally, there has arisen a recognition that mobile phones and their software applications hold significant promise for improving the health of individuals, patient health outcomes and the health of populations [1]. The potential power of mobile technologies when applied to healthcare is significant when considering statistics that reveal close to a 100% adoption of these technologies in the developed and developing world [5,6]. Attention to the mobile health revolution is needed. Researchers need to understand how mobile technologies and their software are used (i.e. through usability testing) and integrated into everyday and worklife (i.e. healthcare related activities and workflows). There is also a need to assess the safety of these technologies with the introduction of technology that causes medical errors. These conditions need to be satisfied to ensure citizen safety and improve patient and population health outcomes [1-4, 7].

To illustrate, in a recent publication by Li et al. the researchers found that usability testing led to the refinement of the software user interface design and improved clinician workflows. This in turn lead to higher rates of adoption of the technology among clinicians [8]. In a study on mobile prescribing systems safety, researchers were able to identify user interface features and functions that led to prescribing errors (i.e. technology-induced errors). In identifying these user interface features and functions and refining the software, potential medical errors were reduced and the costs associated with treating patients who are harmed or injured were also reduced or eliminated [2, 8].

These issues are not limited to software designed for healthcare use. Mobile hardware and software repurposed by citizens and health professionals for health activities can also introduce errors; for example, the autocorrect function on mobile phones may lead to the wrong name of a medication being recorded (if the auto correct changes the name of the medication) while being written into a note taking app on a mobile phone [2,9]. It is for these reasons that usability, workflow and safety of mobile devices and software need to be tested.
What is the Current State of Mobile Device and Software Usability, Workflow and Safety Testing?

Less attention has been paid by researchers and industry to developing new methods for mobile device and software testing for usability, workflow and safety testing [10]. There has also been less attention focused on understanding how mobile technologies’ usability, workflow and safety influence citizen and health professional users in the research literature [11]. There are a number of reasons for this. Perhaps one of the biggest barriers is the mobile nature of devices and the limited development of methods that can be used to test mobile devices for usability, workflow and safety in an effective manner [2,9]. There is a need to develop research methods that allow for recording of audio and video data for analysis of the impact of these technologies in the areas of usability, workflow and safety. Once mobile devices have been refined, we will be better able to understand their impacts upon citizen health, patient outcomes and health professional work processes [9].

In-situ Usability Testing

As mentioned earlier, there has emerged an increasing need to evaluate the effects of mobile device hardware and software from a usability and workflow perspective. Such work is critical to fully understand how the technologies are used to support the health of individuals and populations. “In situ” usability testing, which refers to the collection of usability and workflow data in real-world settings, has become important to understanding how: (a) mobile phone software applications, (b) non-healthcare, mobile phone software applications downloaded by citizens and (c) “true” mobile healthcare software applications are used together by citizens in differing contexts to support health and healthcare [10]. Early work done in this area by Kushniruk and colleagues [10], has often involved conducting usability testing in real-world work settings (i.e. at a computer in a hospital or in a physician’s office). Here, electronic health records and hardware devices used in a hospital or physician’s office are used during usability and workflow testing to ensure the participant feels they are in a real-world environment [10]. Such testing, although effective, is limited by the type of hardware used (i.e. desktop computer or laptop) and is specific to a particular fixed setting by the hardware (i.e. using a desktop computer in a hospital) [11].

With the introduction of mobile phones and software (including healthcare software applications), there has emerged a need to consider and extend existing approaches to usability, workflow and safety testing to account for the ability of citizens and health professionals to move from one setting to another as they perform activities that influence their health (e.g. dietary choices, the choice to exercise) [9]; for example, “in-situ” testing should take place anywhere a citizen may go and use technology to support their health activities [10]. To illustrate, a citizen might use a mobile device and software to support health-related activities in the home, in the car on the way to work, at work, in a restaurant at lunch, at the gym and/or in the physician’s office [5]. This represents a significant challenge for researchers: to collect a fulsome dataset that can be used to improve the overall user experience in engaging in healthcare activities and managing their health, while at the same time collecting information about mobile device hardware and software in these real-world settings [2,10,9,12].

Citizens as Collectors of the Data

Around the world, citizens (e.g. patients, caregivers and health professionals) can now post and view pictures and video online, increasing the potential for consuming and exchanging differing types of health information [13,14]. We have seen rapid growth in the use and miniturization of cameras and audio recorders, and the trend towards supporting citizens, patients and health professionals in recording their own video and audio data (e.g. mobile phones have cameras, video and audio recorders, smart watches have audio recording capabilities, and glasses can be used to record audio and video) for social, recreational, work and educational purposes [13-18]. Citizens are posting health information online, and this information may include textual, picture, video and audio data [13, 14]. Some of these postings take the form of information posts, such as links to health information and posts about self help strategies. Some posts include video and audio data uploaded to social media such as YouTube® and Snapchat® [13,15].

The potential to involve citizens and health professionals in the collection of video and audio usability data using these technologies, due to their miniturized form and integration with other technologies (e.g. glasses, mobile phones, smart watches and social media), is significant [15,16]. Yet, there are few papers that describe the potentials and pitfalls of citizens and health professionals using these ubiquitous tools to collect data in usability, workflow and safety testing (i.e. testing for usability, technology-induced errors and health information technology safety). To date, the focus on such testing has been on mobile devices and software in a traditional laboratory setting [2, 9, 11].

The Challenge of Collecting Mobile Video and Audio Data

Audio and video recordings are essential components of usability testing. Audio data allow one to document verbalizations. If an individual is participating in a usability test, then audio recordings allow for collection of “think aloud” verbalizations or the thoughts of the user as they arise while using a technology, such as a mobile healthcare application [2,11]. Video data in usability testing should include collection of computer screen or mobile device screen recordings [2,9,12]. This is important as it is necessary to be able to view how the user is interacting with the user interface of the technology as they verbalize their thoughts [2,12].

The freedom of movement (i.e. physical and contextual) associated with using a mobile device is significant and poses a number of challenges for conducting research. Mobile device users of healthcare applications seldom stay in a fixed context or position when using the technology. The portability of the device allows the citizen or health professional to move from one location to another and to interact with the device while moving in differing locations throughout the day. This must be accounted for in testing studies. Workflows embedded in the software and workflows associated with using the mobile device and software applicaton need to be captured, and this can be challenging in the real world (i.e. in-situ) [2, 3,10,12].

Existing Approaches Toward Mobile Device and Software Testing

Many methods have been used to collect usability data using mobile approaches. Research methods and factors that influence the quality of mobile usability testing data are
important to consider when designing studies. There are a number of challenges associated with conducting usability tests using mobile phones and healthcare applications [2,12]. One such challenge arises from the recording equipment and the mobile device. The quality of the data collected during mobile usability, workflow and safety tests can be influenced by the type of mobile device and recording equipment/software used. This influences the interpretability of the research results. To illustrate, if the mobile phone is used to record mobile phone screens as the user moves through a software application, hand motions and screen touches will not be recorded. This in turn will make it difficult to determine what the user was touching on the screen at what point in time and if the user interface is confusing [9,12].

In such cases an external audio and video recording device is needed to fully understand what the user is touching on the mobile phone user interface. External devices may require that the mobile phone be fixed to a specific location and position so that all user interactions are captured. This may limit the user’s movement, as well as the researcher’s ability to record the impact of the device and software upon work tasks and activities [2,12].

Some researchers have documented their experiences in conducting usability and workflow testing involving mobile phone hardware and software. In this work the researchers identified a number of issues that need to be considered when conducting such testing, including: data quality issues, the Hawthorne effect and the inability of participants to engage in typical activities and contexts due to the limitations of the audio and video recording equipment employed in mobile phone and software testing. There is a need to attend to the type of audio and video recording equipment used, as this may affect data quality; for example, recording audio and video data directly to the mobile phone of the user does not provide the researcher with insights into what the user is touching on the mobile device screen or what other artifacts and events in the user’s environment are being considered or are influencing mobile phone and software use [2,9,12].

Alternatively, if a user is participating in a test in a usability lab, then data can be captured regarding the user’s interactions with the mobile device using an external camera, but the user’s interaction with their environment is limited to that of the usability lab, rather than the real world (i.e. a citizens home, work or community environment) [10,12]. The user cannot engage in activities that are typical of those undertaken when using a mobile phone in the real world, in-situ setting (e.g. sitting in a restaurant and recording information about one’s meal) [12].

The Future: Using Glasses that Audio and Video Record Data

What is the Potential for Glasses as Video and Audio Recording Devices?

The development of glasses as a video and audio recording tool had its origins in the surveillance [19] and sports industries [20]. In the surveillance industry, glasses that can record video and audio data are used by law enforcement officials to collect data in real time from the perspective of the user for the purpose of conducting surveillance of criminal activities [19]. In the commercial sports industry there emerged a demand for a lightweight, unobtrusive method to collect video and audio data for the purpose of providing the user’s view of sports activities, such as snowboarding, skiing, mountain biking and skateboarding [20]. Users have posted videos for family and friends to share their experiences (with those who were unable to participate) [15,20]. Initially, many of these glasses recorded only video data. Today, they record both audio and video data that can be easily downloaded for review from the glasses [14,15,19,20].

The use of wearable audio and video recording devices has increased in popularity with a wider consumer interest in the technology developing since 2013 [14,15,18]. Approaches have emerged that can be used to effectively collect mobile video and audio recordings for the purpose of assessing the usability, workflow and safety of mobile devices. The idea of collecting audio and video data using glasses has only recently been considered as a viable means of collecting usability, safety and workflow data [21]. In 2013, early work in this area was fostered by Google® with the development of Google® glasses that could be used to present the user with information gleaned from the world wide web, while at the same time providing the capacity to audio and video record data [18]. Wider citizen interest in glasses that record audio and video data increased in 2016 when Snapchat® began marketing glasses that record video and audio data from the user’s point of view. Snapchat® glass users, after recording videos or taking pictures using the glasses, can post digital images and video online via an online social media tool [14-16].

Viability of Glasses as Video and Audio Recording Devices

The viability of glasses as an audio and video recording tool needs to be considered in the context of citizens and health professionals as collectors of video and audio data for usability, workflow and safety testing. Glasses can be used to record audio and video data to capture user interactions with mobile device hardware, software and the real world. When considering the technology for mobile usability, workflow and safety testing one must consider that the technology is used independently from the mobile phone with the user wearing the device. Here, glasses are used to not only collect data about devices and software, but also about how these technologies are used in the context of the user’s surrounding environment [1].

Earlier, the authors of this paper identified there are several types of glasses that perform this activity on the consumer market. Some have been specifically developed for research purposes or for work use (e.g. Tobii®, Google® glasses) . Other glasses have been developed for consumer use (to be used by citizens to record events or sport activities, e.g. Snapchat® glasses). Regardless of the type of glasses used to audio and video record data, there are a number of methodological issues that need to be considered, which we will discuss in the next section of this paper [14-20].

Field of View

One critical issue that needs to be considered when using glasses for audio and video recording data is the field of view. The field of view refers to the extent to which the observable world is seen by the user. Humans have a forward facing horizontal diameter of almost 180-degrees in their field of view [15,18]. In selecting glasses for video and audio recording of interactions with a mobile device and the surrounding environment, it is important to select a device that provides a field of view that is representative of what the user would typically see. The more consistent the field of view is with the users, the more representative the data will be. Some glasses reduce the field of view, thereby limiting the amount
of video data that is collected. Some glass manufacturers have attempted to address this issue by providing glasses with a field of view that is more consistent with the typical user’s field of view; for example, Snapchat®/g glasses have a 115-degree field of view [15]. As the field of view is not consistent across glass types, pilot testing needs to take place to ensure full video data collection.

User Control of Activation/De-activation

One of the key issues in using glasses in video and audio recording data is the activation of the recording function. Different glasses have different approaches to user control of the recording function. This is important if users are asked to wear the device and record interactions. The ability to activate and deactivate the recording function is important from a methodological perspective. Some glasses do this through voice command, others in response to head motions and still others through a touch pad on the glasses themselves [15-20].

In terms of analysis and use of mobile devices for health purposes, the user could activate and deactivate the recording functions of the glasses, recording only when using the mobile device for health-related activities. The advantage of this approach is that the researcher does not have to review hours of video and audio data, and collected data is focused on the activity of interest. To ensure recording device and application use for health-related activities becomes the focus of the study, glass users may need to be trained to record the activities the researcher is interested in studying.

Privacy, Confidentiality and Ethics

From an ethical perspective, the ability to activate or deactivate the recordings at key points in time is critical from a user’s perspective. Here, the user could ask others for permission to record an encounter involving the mobile device, a health app and a health professional or caregiver. Similarly, if the user is unable to obtain the consent of others, the recording could be deactivated by the user. Also, there is the ability to deactivate the recording when the user does not want specific video or audio recorded. To illustrate, Google® glasses can be activated/deactivated through the use of voice commands or head movement at key points in time to enable recording of health-related activities [17,18]. Snapchat® glasses offer another approach to the issue of recording. Snapchat® glasses can also be activated/deactivated through a mobile Snapchat® app [15,16]. Snapchat® affords the user some additional features that may be of value from an ethical perspective. Snapchat® glasses indicate when the video and audio camera is recording to those in the field of view (i.e. a light on the glasses indicates when the recording is on). This may be of value to those being video recorded as they can see when the recording function is enabled and disabled [15,16].

Sufficient Length of Recording Time

Length of recording time refers to the amount of time that is dedicated to recording audio and video data. The recording time needs to be of sufficient length to be able to fully record a health-related activity involving a mobile device. There is a range in the length of recording times for differing types of glasses. Short recording times may lead to disruptions in user activity [9]. This may lead to segmented disruptions in user data or place a burden periodically on the user of downloading recordings to a software application, leading to missing data if the user forgets to download data periodically.

Cost

Cost is a consideration when conducting studies involving the use of glasses. The cost of purchasing glasses that can record video and audio data for usability testing can range from $120 to several thousands of dollars [15, 17, 18, 20]. Glasses used to collect data for usability testing at the upper end of this cost range not only record data, but include analysis software (i.e. Tobii®) [20]. However, involving multiple participants may be costly or cumbersome to coordinate if sharing the glasses between users is difficult. Snapchat® has developed low cost glasses that can be used to live stream and record audio and video data for upload. Snapchat® glasses are priced at $129/pair, and this includes glasses and a charger. Snapchat® offers prescription glasses users the opportunity to purchase a pair of glasses with their own prescription [15,16]. Other glasses used for sports and surveillance purposes that can record audio and video data have also entered the consumer market, allowing for audio and video recording for prices as low as $50, making real-world studies inexpensive and feasible to conduct with large sample sizes [20].

Asthetics

A key issue associated with the use of glasses for recording of audio and video is asthetics. Some users of glasses that audio and video record do not want to wear glasses that differ from other types of glasses that citizens currently wear (e.g. sunglasses, prescription glasses) during the study [15,16,20]. The cost of the technology has been significantly reduced in the past few years (i.e. $30,000) [18]. The cost of the technology has been significantly reduced in the past few years (i.e. $50-100) [20]. The technology is now available at low cost, and there has arisen significant consumer demand for video and audio recording glasses for personal use as a result. Citizens are uploading video to social media (e.g. YouTube®, Snapchat®) to share their experiences and perspectives of the world (i.e. their field of view) [14,15]. Citizens are now capable of collecting usability, workflow and safety data about the mobile hardware and software they use for health activities. There is a significant opportunity to employ consumers in the process of collecting research data. As the cost of the technology has decreased, there are opportunities to increase the sample size of usability, safety and workflow studies and for these studies to take place in real-world contexts.

Future Research Directions and a Future Vision

Glasses that audio and video record data offer significant advantages over traditional recording techniques used to collect usability, workflow and safety data. Such glasses allow one to record the user’s interactions with the mobile device hardware and software (i.e. health app and mobile phone app software). In addition to this, the glasses can record user interactions with their environment, in context and how the mobile technology is used within that context, as recorded in the field of view of the glasses.

Historically, glasses that audio and video record were costly (i.e. $30,000) [18]. The cost of the technology has been significantly reduced in the past few years (i.e. $50-100) [20]. The technology is now available at low cost, and there has arisen significant consumer demand for video and audio recording glasses for personal use as a result. Citizens are uploading video to social media (e.g. YouTube®, Snapchat®) to share their experiences and perspectives of the world (i.e. their field of view) [14,15]. Citizens are now capable of collecting usability, workflow and safety data about the mobile hardware and software they use for health activities. There is a significant opportunity to employ consumers in the process of collecting research data. As the cost of the technology has decreased, there are opportunities to increase the sample size of usability, safety and workflow studies and for these studies to take place in real-world contexts.

There remain a number of challenges in conducting such research. Researchers need to understand the audio and video recording glasses they plan to use for such research, as they vary along a number of dimensions. For example, the field of view is different depending on the type of glasses used and glasses may have differing lengths of time that the technology records video and audio data. Privacy, confidentiality and
ethical issues are also present, as some users may not be comfortable with recording health-related activities and others in their immediate context or environment. This is linked to the visibility of such glasses as recording devices; for example, Google® glasses [20] were observed by others in an individual’s context as recording devices, whereas Snapchat® glasses are similar to spectacles or sunglasses [15]. Additionally, advances in analysis of video data will be needed as recording using glasses could potentially lead to large data sets.

There are many challenges associated with using glasses that can audio and video record, but they do represent a significant advance in the area of mobile usability, workflow and safety testing as they allow the researcher to see how technology is used in real-world settings, capturing information about user gestures, activities and interactions with the mobile technology and their environment. As this represents a significant leap in recording devices, future research will need to focus on how to analyze user interactions between mobile devices, software and others in the healthcare setting. Such information will be critical to refining existing mobile hardware and software used by consumers for health-related activities. The work will lead to technology designs that have greater and more seamless intergration and support for healthcare activities within the context of the users’ worklife and their lifestyle.

Integrated Care Processes Designed for the Future Healthcare System

Thomas Bürgkla, Kerstin Denecke, Michael Lehmann, Erwin Zetz, Jürgen Holma

*Institute for Medical Informatics, Bern University of Applied Sciences, Bern, Switzerland

b GS1, Bern, Switzerland

Abstract

Previous studies showed that a stronger focus on integrated care models is required, targeting at a seamless coordinated care reaching patients even at home and thus establish patient centered and patient driven innovation activities. Such integrated care model is important among others for ensuring traceability that is necessary when problems during treatment occur or in cases of product counterfeiting for ensuring patient safety. The objective of our work is to realize an efficient, continuous care process, considering an optimal, end-to-end treatment path. In this paper, we describe the process how to pave the way for developing technologies for realizing a cross-sector treatment pathway. Following a multi-stakeholder principle and by applying requirement analysis and world café methodology we designed first concepts and strategies.

Keywords: Healthcare; Patient Safety; Telemedicine

Introduction

“Prognoses are difficult, especially when they concern the future”, this sentence has been attributed to the Danish physicist Niels Bohr (1885-1962) in a lecture in Copenhagen. Nevertheless, prognoses for the future of hospitals, their organization and their technology have been made at all times [1]. In a recent report of the Spanish center for research in healthcare innovation management, two leading European university hospitals have been analyzed and a set of future challenges for such sites have been derived [2]. They include increasing demands combined with decreasing resources, smaller and more complex hospitals, the demand for new services such as personalized medicine and a future duplicate role providing complex care as well as acute services for the catchment area. The authors emphasize the need for knowledge driven redesign of efficient services, the requirement for distributed organizational structures and the trend towards technology driven healthcare service innovation. They foresee a stronger focus on integrated care models, a tendency towards seamless coordinated care reaching patients even at home and thus patient centered and patient driven innovation activities [2]. A strong focus on modern information technologies in hospitals is undisputed [2, 3]. In the UK, a future hospital commission has been funded by the royal college of physicians and finalized their report devoting a complete chapter to improved information technology [4, 5]. Some of the identified technology trends include connected medical devices, quantified health data, medical records on-the-go, on-call doctors via telehealth and 3-D printing [6]. In view of limited resources, prevention and early risk detection will become a prime focus and eHealth platforms may complement today’s mostly curative approaches to medicine. New forms of care will emerge, in which the patient will make self-determined decisions and will be able to self-manage his personal health.

The institute for medical informatics (I4MI) of the Bern University of Applied Sciences BFH, and GS1 Switzerland, a non-profit professional association for optimizing value added process chains cooperated in a first project “Hospital of the future” to develop a concept for innovative future healthcare based on today’s available information technology [7]. Now, the second project phase has been started under the title “Hospital of the future live”. We follow the vision that information relevant for the treatment of a patient will be available to all authorized actors at the point of care in a secure, reproducible and appropriate manner. This includes not only an accurate documentation of the services and materials provided to the patients, but also improved workflows where resources and required materials will be available just in time for medical procedures.

We try to realize the vision of an integrated care model that reaches the patient already at home with a variety of projects along a typical treatment pathway. Results are implemented in our comprehensive I4MI medical informatics laboratory and in real environments to demonstrate an optimized treatment pathway and information workflow of the future. Here, we introduce the overall methodology of the project and demonstrate first results.

Methods

Both projects, “Hospital of the future” and “Hospital of the future live” have been organized as multi-stakeholder projects. The first project started in 2012 with a visionary brainstorming process focusing on the Swiss healthcare environment with the partners GS1 and économiesuisse, the holding organization of the Swiss economy organizations. Following the brainstorming process, an in-depth analysis was performed to determine the required medical activities for a virtual elderly and multi-morbid patient requiring hip surgery and implantation of a total endoprosthesis (TEP) for advanced arthropsis. The project maintained an advisory board with participants from hospitals, IT industry, pharmaceutical industry and medical product suppliers. Multi stakeholder table technology was employed to gain insights into the current and a possible future improved care process.
“Hospital of the future live” started in 2016 with initially 21 partners, including six Swiss hospitals, four major IT suppliers, IHE Suisse, IHE User Group Switzerland (http://www.ihe-suisse.ch) and eHealth Suisse, the coordinating body for the implementation of the Swiss eHealth architecture [8]. The project runs coordination meetings to define and prioritize punctual areas of activity along the patient pathway in shape of atomic work packages (WP). A total of 6 major coordination meetings with all participants have been scheduled until 2018 for this project. WPs are grouped into activities prior to hospitalization, WPs during hospitalization and WPs downstream when the patient has returned home. In the coordination meetings, the participants passed through parallel sessions in which an expert explains each WP. They had then to vote for the prioritization of the work, and commit themselves if they will participate actively in the respective WP. From this voting, we selected the most relevant WPs which in turn were condensed to projects which may comprise between one and six WPs. These projects are further outlined and distributed to the more advanced students of the Bachelor study of medical informatics at the BFH. In shape of seminar and so called living case (practical courses) topics in which requirements from the relevant stakeholders are collected, including current processes and ideas on improved process flow, target states are specified and prototypes are implemented as basis for future product development.

Living cases will result either in a working prototype or an implemented piece of software, which is installed in the I4MI medical informatics laboratory to demonstrate a potential solution for the problem. Within seminar projects, the students have to analyze requirements in detail with the stakeholders, to develop a feasible IT concept to solve the determined interoperability problems and to describe and present this work. For the coordination of the different student activities, we use the world café methodology, which helps to identify future visions for selected processes.

Typically, a successful living case work may be continued towards the bachelor thesis which should result not only in an IT based implementation, but also in a formal evaluation of the developed solution in a real environment, e.g. a hospital department, a medical surgery, a rehabilitation center or a community care organization.

Results

First study

Results of the first study “Hospital of the future” included a document which described the patient’s current clinical pathway from home to home across several care providers and institutions comprising many process gaps and inefficiencies in today’s Swiss healthcare system and contrasted this with a visionary future clinical pathway avoiding most of these gaps and information loss [7].

The study demonstrated that Swiss hospitals are not sufficiently integrated into the entire information flow. Integration of data and processes towards the outpatient sector and the supplier is yet rarely realized. A closer look at the flow of information in the Swiss healthcare system demonstrated that, in many places, the knowledge about the patient is locked in single information systems instead of being integrated among systems to get the whole picture on the health of a patient which is necessary when making personalized clinical decisions. The study demonstrated the need for a better linkage between medical activities along the governing clinical pathway and accompanying processes starting from the admission into a hospital to discharge, including the supply chain. Particularly those processes were closely investigated, in which the dispensing of medication and / or medical equipment or consumables were involved.

In addition, interruptions in the logistic information flow for drugs or materials themselves, which would permit establishing a continuous supply chain, have been analyzed. Such traceability is necessary when problems during treatment occur or in cases of product counterfeiting for ensuring patient safety. In many Swiss hospitals, however, the supply chain for materials is broken between the different internal storage places such as ward cupboards for medical supply or drugs. Often it is unknown, when, where and how drugs, consumables or smaller devices are ordered, consumed or stored, potentially resulting in drugs with exceeded expiry date in stock or insufficient trace back of defects in instruments or devices. This can lead to serious consequences in security and patient safety.

To achieve a better common understanding of complex information flow e.g. in the medication process, an easy to understand process tool named IXPRA (Figure 1) has been developed to support process analysis tasks in a multi stakeholder environment [9]. IXPRA stands for Interface Cross Culture Process Analysis Tool and is a toolset which describes medical processes on a functional level with main processes, sub-processes and particularities, but also on an application level resulting in clinical use cases and on an interaction level comprising involved staff, involved IT systems and special challenges. The functional level describes the basic process steps, sub-processes and comments. The application level describes the use cases or a task description with the relevant process steps. The interaction level displays involved people, IT systems and special features. Using IXPRA, the problems and challenges within a process can be identified. The results of an IXPRA process analysis form the basis for discussions with involved people and for developing new solutions that improve the processes. IXPRA enables rapid focusing on the information gaps and information loss and supports especially weakness analysis. Besides the concrete process analysis, factors such as the possible influence of management decisions and the internal incident culture of the processes can be examined. Today, an IT based implementation of IXPRA is available from MID GmbH Nuremberg, Germany.

Within the first study “Hospital of the future”, IXPRA has been repeatedly used to analyze e.g. weaknesses in the medication process at hospital partners such as the Spital Thurgau AG and Spitalzentrum Biel. We found considerable weaknesses in the investigated workflows, e.g. concerning the medication process. Currently, the information flow is broken in different dimensions as it was identified for the care process in the outpatient sector: information on the patient him/herself; information on instruments / material is collected – if at all – in separate information systems. This causes a high risk for patient safety, outcome quality and limits efficiency of workflows. In tangible terms, our goals for the second study are:
Several limitations could be identified in this care process:

1. Realizing a cross-sector treatment pathway,
2. Integrating eHealth and demonstrate potentials of eHealth and
3. Realizing new use cases and derive business cases.

Second study

The second study “Hospital of the future live” started in June 2016 and is planned to last for two years, thus only preliminary results are available at the time of this paper. The second study builds upon the results of the first study including the detected weaknesses. So far, two of six planned multi stakeholder coordination meetings have been completed, the first one in July 2016. In this meeting, a set of 59 WPs has been jointly defined and finalized. They include:

- 18 WP prior to hospitalization. An example is the following WP: Given the situation that a patient suffers from arthritis and also from diabetes. How can his diabetes management at home be improved using the future Swiss eHealth environment (new legislation for a countrywide electronic patient record in Switzerland)? This includes setting up a connected diabetes monitoring platform on mobile devices and establishing appropriate monitoring mechanisms to avoid hyper- and hypoglycaemic episodes.
- 21 WP center around hospital care and treatment. An example WP deals with the information flow between acute hospital care and rehabilitation care for the remobilization of the patient. The task is to examine and demonstrate which data and information can be transferred in a structured fashion across the Swiss eHealth environment between both institutions.
- 14 WP deal with the patient’s downstream home activities and the logistics linkage. It can be expected that stronger efforts will be made to support citizens to continue living in their home environment, aided by AAL (active and assisted living) activities such as an intelligent wardrobe in their home environment [10]. As an example of this type, consider a WP where we will examine the required activities and information workflows for the re-initialization of the home environment digital devices when the patient returns and may have different gait patterns which should not lead to unnecessary alerts of the fall detecting floor in his/her apartment.
- 6 remaining WPs enable us to build the required infrastructure within our medical informatics laboratory to support those activities. Within one WP, we will establish a generic middleware for connected sensor technology.

With the methods outlined before, we aggregated a first set of 28 highly prioritized WPs into 12 student projects (Figure 2).

A preliminary result concerned the preoperative handover between GP, orthopedic specialist and hospital. The current outpatient care process was analyzed with the goal to eliminate weaknesses and to derive an innovative IT-driven process. The result of the process analysis is shown in Figure 3. Several limitations could be identified in this care process:

- Referral forms are filled by hand and sent by fax.
- Reports from the orthopedic specialist are sent by fax and re-entered into software at the GP.
- Image data is transferred by the patient (manual transport of discs).
- Reports from the hospital are sent by mail.

These issues lead to information loss. Within the student project, several improvements have been identified:

First, the information system at the general practitioner (GP) could be enabled to recommend appropriate specialists, rehabilitation centers, hospitals and pharmacies, which are specialized for the medical problem of the given patient. Relevant criteria might be distance to the patient’s home location, experience in treating hip arthrosis, free capacity, and information about the available surgeon(s). This would save resources in searching for relevant specialists.

Second, using an eHealth platform with access for all relevant persons of the care team can help avoiding such limitations. Each report and examination result can be made available through the platform and authorized persons can access the data directly from there. Third, appointments with the orthopedic specialist could be made directly with IT from the GP’s place. Fourth, patients could rate the treatment for each provider through an online portal. These ratings could be made publicly available for decision making and quality assessment.

Discussion

The digital transformation is finding its way into the various national healthcare systems. E-Health strategies have been developed in the last years in multiple European countries such as Germany, Switzerland or Austria [11]. These strategies aim at improving the availability of treatment-related patient data beyond sectoral borders. But even before these goals are reached, we see the emergence of new requirements such as personalized medicine, big data, or intelligent self-monitoring devices with a yet unexploited potential to detect diseases earlier and prevent adverse events.

On the other side, all civilized nations are faced with ever increasing healthcare costs, an ageing population and the breakup of traditional family structures. We need to use the potential of modern information technology to ease these effects and to enable elder citizen to stay in their familiar home environment as long as possible.

A specific problem in the healthcare sector is that the treatment process consists of complex workflows, where many actors and IT systems are involved to achieve the most efficient and effective treatment of a patient. The processes in this workflow extend beyond the classical clinical pathway which covers the workflow within a single institution such as a hospital. Instead, it is essential to include also processes outside the hospital such as early diagnosing at the general practitioner, and collection of personal health information in the intelligent home, as well as downstream processes and the interlinked logistic activities. Benefits of such an integrated care process are manifold and can include:

- Individuals become actively involved in the treatment processes and become able to self-manage their health.
- The family medicine, pharmacy, rehabilitation or nursing services profit from new, integrated IT processes.
- Healthcare providers are provided with more support in treatment planning and better provision of pharmaceuticals and materials.
- The entire logistics chain and the participating industrial partners achieve more transparency regarding the flow of goods and consumption of goods.
- The administration can improve cost center accounting.
- The hospital as a whole benefits from optimized processes and efficiency improvements, which are an additional competitive advantage.
- The ICT industry partners are enabled by mapping future workflows that involve mobile devices and other upcoming technologies within ICT healthcare system.

We are confident that these results as well as the IXPRA method will help us to focus on promising improvements within the treatment chain. The WPs and subprojects of our efforts will result in the development of prototypical IT installations in our medical informatics laboratory, which help to understand the effect and the extent of the potential improvement which can be achieved. We can perform IT development, evaluation and verification of processes and technologies in this environment without causing harm to any person.

Obviously the next step must be a practical evaluation also in real environments and this is a declared goal for the project “Hospital of the future live” which shall give good indicators regarding the flow of goods and consumption of goods.

Physicians and healthcare professionals may have (legitimate) reservations against new technologies workflow alterations, often in the interest of their patients. Introducing new treatment paths with support of modern IT technology requires careful action and a change management approach. We need to demonstrate and verify the potential improvement first before asking for change and our approach should enable us to do so.

**Conclusion**

The triggering question in this work is: How can medical informatics influence the care process and the care network positively in the next five years? We address this question by developing innovative ideas for the future healthcare processes and by showcasing them in a living lab. In this paper, we provided an overview on a suite of projects targeting at 1) identifying limitations in processes of current healthcare systems and 2) developing solutions for designing the future healthcare system. Our goal is not only the improvement of the care process by enabling a continuous management and data integration, but also the transparent integration of the supply chain with the care process. The upcoming results of the WPs will be presented to the stakeholders and wherever possible, the results will be implemented in the real world after comprehensive testing in our labs.

Design and Evaluation on the Mobile Application of Transcutaneous Electrical Nerve Stimulation (TENS)

Ching-Lung Cheng, Li-Hui Lee, Yu-Ting Cheng

Department of Health Care Management, National Taipei University of Nursing and Health Science, Taipei City, Taiwan, China

Abstract

This study aims to design a transcutaneous electrical nerve stimulation Application (TENS App) according to the suggestions from potential users. To the best of our knowledge, this is the first App including meridian and acupoints for TENS. After its development, there are eight participants recruited for evaluating the usability. Despite two out of eight users reporting that the typical TENS system requires lower cost and has better functionality than TENS App, the results show that almost seventy percent of participants have a better perception of TENS App on price, functionality, convenience, operational ability, and quality. However, participants still reported concerns about the safety issue of adopting TENS App. Therefore, for people who are the first time or unfamiliar with TENS App, instructions from occupational or physical therapists are recommended. We conclude that by using TENS App, users can not only use the portable electrotherapy devices at anyplace, but also reduce their outpatient visits.

Keywords:
Electric Stimulation Therapy; Smartphone; Mobile Applications

Introduction

Pain is the unpleasant feeling induced by illness, physical impairments, or harmful outer stimuli. The two major causes of pain include the activation of stimuli to nociceptor and impairment of human nervous system. Nociceptor receives chemical, thermal, or forceful stimuli which damage human tissues and transmits painful sensation to the nervous system. And if the nervous system is impaired due to injury or illness, it will induce neurological pain or neuropathy.

Past related studies found evidence to support short-term physical therapy intervention to be effective in relieving knee joint pain or joint arthritis pain. It is also recommended to provide intensive treatment program using transcutaneous electrical nerve stimulation (TENS) with pulse rate setting between 1Hz to 150 Hz, a minimum of 20 minutes as treatment duration each session, for a minimum of 5 sessions, in a period of two to four weeks[1-3].

Clinical physical therapy relieves pain based on the Gate Control Theory (Figure 1). Based on this theory, TENS device utilizes subtle low-frequency electronic current to stimulate epidermal nerves [4]. The signals from the device are transmitted faster than pain signals, which arrive at the “gate” first and block the pain signals from passing through, thus reduce the pain perceived by the brain. TENS has been extensively used by physicians and therapists in physical medicine and rehabilitation (PM&R), and most of the TENS devices apply electrical stimulation to skin tissues, using low-frequency pulse rate changes to induce the release of pain relief substances from central nervous system.

Figure 1 – Gate Control Theory.

TENS for pain relief requires customization according to the characteristics of pain, and it requires regular intervention. Physical therapy intervention with TENS devices involves with a professional assessment and adjustment protocols. Patients usually can only receive the services in clinics or hospitals. Despite its effectiveness to relieve pain, the accessibility of TENS is insufficient. Therefore, some companies such as Panasonic, Koka, Tatung, and Omron have been selling similar products for patients to use at home. Most of the devices can be operated through the equipment interfaces but few devices can be handled or configured by App, such as iTENS [5]. Moreover, these few Apps do not show the meridian and acupoints to precisely guide users in the use of pain patches. Also, there was a noticeable absence of research projects dealing with the usability of Apps for TENS.

Moreover, the portable electrotherapy pain relief patches using the latest technology have appeared on the market. The new product applies professional TENS technology to a thin pad design. It is compact in size and reusable with power saving technology, providing users more convenience and reducing waste from traditional disposable pain patches. This also presents an opportunity to design a new health information technology with portable TENS. This study aims to design a TENS App including meridian and acupoints information and then to assess its usability in five dimensions (price, functionality, convenience, operational ability, and quality) and do the comparison between the typical TENS device and our TENS App with summarizing their advantages and disadvantages.
Literature Review

This study reviews articles regarding the medical concepts behind TENS, myofascial pain, and related physical therapy intervention, as well as the clinical application of TENS systems. It aims to summarize the studies and understanding on TENS systems.

Medical Concepts behind TENS

TENS product has been widely used for palliative care in developed countries, including the non-noxious or acute pain from malignant neoplasms or related medical treatments. The product is safe, low in cost, and free from serious side effects. Under the directions of a physical therapist, people with muscular pain or patient with needs could operate the product at home and receive short-term pain relief effects. Therefore patients could apply two self-adhesive patches on their skin, and use the low-frequency electrical stimulation with control of set protocol safely [1].

Literature reviews found that the first records of using electrical stimulation to relieve pain date back to a Roman physician [2]. In 1786, the Roman physician experimented on the frog leg and proved electrical stimulation can relieve pain and reduce muscle tension. The observation along with the progress of power generation further urges the use of electrical stimulation to treat various diseases and relieve pain. In 1965, Doctor Ronald Melzack from Monterey, Canada and Doctor Patrick Wall from England published the focus treatment mechanism in University of London. Their mechanism is that the central neuron system modifies the quality and quantity of neuron signal from the peripheral neuron system to the brain[3]. Based on the Gate Control Theory, they proposed that by selectively utilizing low-frequency electrical stimulation to large diameter nerve through skin tissues, transmission of pain signals could be inhibited and thus reduce pain perception.

TENS devices are usually made of a single line (two electrodes) or two lines (four electrodes). There are potentiometer or regulator on the devices for the users to adjust the stimulation intensity. The stimulation variables include wave formation, frequency, and intensity. In sum, when utilizing TENS devices, chronic patients can choose protocols with low frequency and high-intensity stimulation, while acute patients are recommended to use protocols with high frequency and high-intensity stimulation.

Common myofascial pain and related physical therapy intervention

Myofascial Pain Syndrome is not a specific disease. Instead, it is a syndrome caused by extensive muscle tension. If the muscle is under tension status for a long period, it will impede peripheral blood flow and thus impedes the circulation system to take away waste productions from metabolism mechanism such as lactic acid. The accumulation of lactic acid in specific parts would then induce soreness and discomfort. Therefore, Myofascial Pain Syndrome is one of the common causes of low back pain.

If human body keeps in the same position for a long period, there must be a group of muscles stay in tension status for a long time. As time goes by, Myofascial Pain Syndrome occurs with muscle soreness and fatigues. Different from medical diagnosis by physicians, physical therapist evaluates and assesses patients using structure diagnosis, providing a diagnosis of somatic dysfunction and setting intervention plans accordingly. In general, physical therapist diagnoses patients under the three principles A-R-T:

- Asymmetry (A): Physical Therapist assesses patient's symmetry on the musculoskeletal system through palpation and observation.
- The Range of Motion (R): The assessment focuses on the range of the movement and its movement quality of a single or multiple joints, such as hyper- or hypomobility. The patient follows directions to check the active and passive range of motion at different joints.
- Soft Tissue (T): Physical Therapist evaluates abnormal soft tissue textures, including skin, muscle, fascia, tendon, etc.

Clinical Application of TENS System

The clinical experiments had proved a regulation rule for pain treatment. The Randomized Controlled Trials (RCTs) in the early period indicated that many patients used TENS to treat focal pain and acute pain. Carroll found that TENS did not relieve pain after surgery because no significant difference was found between the experiment group and control group on pain relief [4]. Researchers suggested that TENS could relieve chronic pain. Although this was a commonly accepted concept, current studies on TENS are not extensively enough to provide sufficient evidence on its effectiveness for rheumatoid arthritis, neck disorders, or chronic low back pain [6]. On contrast, several RCTs have provided evidence for TENS on treating pain symptoms for knee joint arthritis [7] and chronic skeletal muscle pain [8]. Some researchers report that TENS can improve pain symptoms for some patients with chronic disorders including focal muscle pain, postherpetic neuralgia, trigeminal neuralgia, phantom limb pain and diabetic neuropathy. Therefore, applying TENS to muscle inflammation on ipsilateral or contralateral parts is likely to reduce the chronic pain response over bilateral limbs caused by unilateral inflammation [9].

Methods and Study Subjects

TENS App Mechanism

If blood flow and massage could alleviate the pain, it is seen as the effect of relaxing muscle pain. This App could transport the electric energy from the device to muscle via the audio card in the smartphone. Users could easily attach two electrode pads on their skin surface to conduct energy. The electrotherapy can alleviate the pain and relax the strained muscle through the muscle layer. Then the power improves the blood circulation to decrease pain substance in the body. Both mechanisms have the pain alleviating effect.

Different low-frequency current has a different effect on alleviating and relieving pain. The effect is caused by activating neural functionality and the power of body fluid as well as increasing blood flow in the body to gradually decrease the muscle hypertonia. TENS App provides multiple functionalities which can easily control the current mode, time duration, and intensity. Users can configure its functionalities to active the effects of rhythmic muscle contraction on unbalanced muscles.

TENS App Design

Authors make many principles for the interface design to maximize the operational efficiency. The design principles include the visualization, feedback, response, synchronizing, and responsibility. We could improve and raise convenience in the TENS equipment through replacing the traditional TENS...
devices by the interface on the smartphone. The study is based on the interview with a focus group [10]. After TENS App is developed, we invite those study subjects who have at least one year experience of using other TENS system to join the study. We have an interview with the study subjects for 60 to 90 minutes in a semi-constructional way. Then we can summarize the features for the prototype interface which can fulfill with designer’s requirement. Furthermore, we can find out its advantages and disadvantages.

**Method and Subjects**

The study subjects who finished the questionnaire were aged between 20 and 50, with myofascial pain syndrome on upper back and neck, and pain lasting for at least one week. We excluded patients have operation history on the upper back, neck or vertebra. We invited 10 subjects for the interview through purposive sampling[11; 12], eight respondents finished the interview. Participants were contacted in order to explain our research purpose. After we had their agreement, we had an interview by questionnaire with every single one to listen to their experience with using the TENS App. All participants had taken the typical TENS (X brand) therapy and TENS App self-relax therapy for four times within two weeks. All participants were evaluated by a five-dimension questionnaire which is modified according to Liu’s [13]. These five dimensions are in regard with users’ opinion on the price, functionality, convenience, operational ability, and quality. We used their feedback about these two devices to evaluate their effects.

**Results**

**TENS App Design**

The App primary functionality includes a brief instruction film about how to use the system, a Chinese medicine acupuncture point and symptom chart, a symptom and acupuncture chart for office workers, a symptom and acupuncture chart for students, male common symptom and acupuncture point chart, female common symptom and acupuncture point chart, Chinese medicine meridian charts and reflection area lists. The homepage combines all symptoms with acupuncture points based on Chinese medicine theory. It could help users understand the relationship between the symptoms and acupuncture points (Figure 2).

We upload the instruction film on the Internet for the purpose of publicizing and advocating this product to more people and providing users an easy know-how for using this product. The built-in homepage in App also helps the first time users and individuals who are interested to know more about this App and detail (Figure 3).

The system is designed to activate the TENS operation mode automatically when the earphone connects to the smartphone. The purpose of TENS interface in this system is to provide an appropriate stimulus wave, frequency, duration and power export. Users can undergo their physical relaxing therapy at home based on their status and physiatrist or physical therapist’s instructions. The duration in the system is between 10 to 60 minutes. There is a total of three different modes for users in the electrotherapy setting mode. The operation interface provides 13 levels of energy (Figure 4).
Also, the built-in main symptom and acupuncture points charts show the users where the correct points are to relieve the pain on the body (Figure 5). The terminal of this device has two electrode pads attached to the human skin to relax the pain in muscle layers by electrotherapy (Figure 6). Its convenience lies in that it can increase the patient’s willingness to do the portable electrotherapy at home.

Demographics

In total eight respondents used similar typical TENS devices and responded to the questionnaire. The basic information is presented in Table 1. There were six female and two male respondents aged between 28 and 50. Their career sectors included service, catering, public affairs, and construction industry. There were four managers and four office administrators.

Assessment

This study used the X brand a conventional TENS device on the market and TENS App (named as App) to do an assessment analysis. The study endpoints in the evaluation are in Table 2. Almost seventy percent of respondents (67.5%) have a better perception of price, function, convenience, operation, and quality in operating TENS App, even two of respondents believed that the X brand device has better price and functionality. There are some suggestions from users such as the professional assistance or instruction from the occupational therapist or physical therapist to operate TENS App for the first time user. The user should use TENS App according to their pain status to alleviate the pain correctly and safely.

Discussion

We only took consideration on Asian user’s experience from eight study subjects with their agreement. All potential users’ feeling can not be generalized. This study could help TENS App’s upgrade and development in the future. So far we could not figure out the issue about the automatic detection of human acupuncture points. We suggest that it could compare our result with the big data to understand more about the relationship between the currency frequency and time duration. That information could help users improve and relax their body even faster. Moreover, we suggest that users could play music with the therapy for relaxing and balancing their mind.
Conclusions

Based on the comparison between the typical TENS device and TENS App, we find that participants are more focused on quality and convenience. TENS App has much better performance on these end points than the conventional ones. TENS App also has more advantages on the price than the regular ones.

To our knowledge, this is the first TENS App that was installed on a smartphone with the Chinese medicine acupuncture point charts. This helps users to find the correct position immediately that could help relax the strained muscles and relieve the pressure quickly. Furthermore, because of the high use rate of the smartphone around the world, it is possible to advocate and advertise the use of TENS App widely.

In Search of a Digital Health Compass to Navigate the Health System

Catherine Chronaki\textsuperscript{a}, Robert Stegwee\textsuperscript{b,c}, Anne Moen\textsuperscript{d}

Abstract

Healthcare systems increasingly rely on digital technologies to sustain costs and improve access to quality care. Data drive a wave of automation aspiring to improve productivity by forging connections between health and wellness, medical research, and clinical decision support. Mobile apps and patient-generated data combined with provider recordings pave the way towards personalized care pathways and just-in time access to health services. Navigating the health ecosystem becomes challenging as roles and relationships change. This paper reflects on the digital health compass to navigate the health system using one’s own data. Health information technology standards are at the core of the compass, to tap the potential of shared aggregate data and sustain trust. The notion of the patient summary as a window to one’s health is used as an example to drive our call for action for health informatics to develop methods to calibrate the digital health compass and feed on ‘my data’, respecting ‘my decision’, to fuel ‘our ePower’.

Keywords:
Telemedicine; Reference Standards; Personal Health Records

Introduction

Knowledge is power. Despite extensive investments in digital health technology and incentives for uptake of eHealth consumer services, navigating the health system online is hard. The 2014 digital health literacy survey confirms differences and widening divides \cite{1}. The “Inverse Care Law” proposed by Hart in 1971 \cite{2}, seems to apply to eHealth. Availability of, access to, and productive use of advanced medical or social care services and digital health tools, varies inversely with the needs of the communities. In fact, the low adoption of digital health technology and eHealth services among segments of the population underscores persistent disparities in health care.

Barriers and challenges are not to be underestimated as people feel that with excessive use of technology we may lose the human touch. Taking into account culture, education, skills, costs, perceptions of power and role, is essential for successful community actions. These elements come together in digital health literacy, “the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to address or solve a health problem” \cite{3}, which underpins the knowledge and skills required to construct the digital health compass to navigate the healthcare system. Patients living with an implanted device, coping with chronic disease, engaging in self-care, caring for an elderly relative in deteriorating health, or an ailing child, need a digital health compass. Hyper-personalization enters every facet of our life and personal data on health and behaviors can be used to present information and knowledge, services, and tools, at the right time and in the right way \cite{4}.

There is an ongoing shift in the terrain of the health sector from cure to care, where patients, families and informal care givers actively participate. This may be because they want to help \cite{5} or they are expected to make health decisions \cite{6,7}. We argue that citizens need a digital health compass to unlock the power of their health information, drive their engagement in personal health information management, and identify the most suitable health services for the situation at hand. With the increasing quantity and uneven quality of health data, patient summaries could be the starting point to write an individual’s health story.

Patient summaries can point to key information accumulated across health systems, sites and care settings and essential information in planned and emergency encounters. However, this assumes a joint effort to clarify expectations and keep patient summaries accurate and complete \cite{7,8}. The Trillium Bridge project recommended a patient summary standard for people to access and share their health information and to drive incentives for quality record keeping and health professional appraisals \cite{1}.

Attending to data provenance, patient summaries complemented with patient-generated data can supplement health services and facilitate a smooth transition to digital health. High quality patient summaries can foster safe and effective care for or by an individual in a variety of situations. For example, we may offer our patient summary during an emergency hospital admission. We may use them to seek a second opinion or search health information online, or just to connect health professionals that typically do not exchange information or cooperate.

Experienced users may employ patient summaries in connection to personal health records to monitor their health and engage in health decisions. They may collect personal observations to complement or expand on existing data, to support self-care and follow up on health management activities. A data culture would take us further, to where we use patient summaries to safely engage in personalized navigation of the internet and network with people facing similar health issues.

Progress however, is slow. Reasons can be summed up with low digital health literacy. For the most part, patients and informal caregivers are not excited by available digital health tools. Either they do not trust them, or do not know how to use them. To make matters worse, many health professionals are not comfortable with recommending specific digital health tools to their patients. Limited sharing of information and under-developed cooperation among patients, informal care givers and health care professionals leaves un tapped the potential of data for informed health decisions. Resistance is fueled by the need to protect our privacy, dignity, integrity, and individuality. Where

\textsuperscript{1}http://ec.europa.eu/newsroom/dae/document.cfm?doc_id=11039
the Internet of Things (IoT) meets health care, a plethora of tools, gadgets, and apps overpromise and under-deliver on improving health and wellness and supporting an active lifestyle. They score low in actionable knowledge, partly because disconnected from health and social care services, they hinder personal efforts to share intimate information, while preserving one’s self-reliance, autonomy, and freedom of choice.

The rest of this paper is organized as follows. The next section presents the vision of the digital health compass and its relation to health information interoperability standards that link fragmented sources of information. The case of the patient summary illustrates how the compass may work from the perspectives of health systems, eHealth consumers, the healthcare workforce, and the eHealth market (see Figure 1). Then, “my data”, “my decision”, “our ePower” complete the vision of the digital health compass with a call for action to the medical informatics community that can help shift the narrative towards safe and trusted use of health data to benefit individuals and the society as a whole.

Figure 1 – A Digital Health Compass to Navigate the Health System.

Digital health compass

A digital health compass with knowledge of a person’s digital health literacy profile can point to eHealth resources that foster personal control and empowerment. Different dimensions need to be considered to understand how a digital health compass can support safety, prevent harmful events, and assist in managing efficient, connected services of high quality and relevance in the digital health ecosystem. Health data standards, open interfaces, and a culture of sharing increase trust. Complementary initiatives to health information technology standards are the Dublin Core Metadata Initiative (DCMI) headings, the HONcode labelling online health resources, and W3C guidelines for usability and accessibility building confidence in navigation.

Standards in the digital health ecosystem

Health information technology standards are required to provide common metadata about digital health products and assemble fragmented information scaling up and sustaining digital health literacy [5, 9]. Standards developing organizations work together on standards to meet the health information needs of people within and across health facilities. The value of data and the increasing focus on patient experience, dictates global cooperation on open standards emphasizing mobile use.

HL7 FHIR

In HL7, this trend is reflected in Fast Healthcare Interoperability Resources (FHIR), a new standards initiative seeking to liberate data for population health and precision medicine in the context of learning health systems. FHIR is based on a set of modular components or Resources, which are small discrete units of exchange with defined behaviour addressable using URIs. Resources are combined into profiles to solve practical clinical and administrative problems. Resource extensions and profiles facilitate the addition of data that are not part of the core, which follows the 80/20 rule i.e. cover the top 80% use cases and most frequent functionality. The overall approach is web-based (i.e. RESTful API), service driven, and supports adaption and portability of components moving program code with data as resource bundles. A robust FHIR resource maturity framework tracks the stability and extent of world-wide adoption of every resource. The version of FHIR balloted in 2015 (DSTU2), includes 27 clinical resources along with supporting financial, conformance, workflow, identification, and infrastructure resources. The high appeal of FHIR can be attributed to its vibrant and committed implementation community, available tools, services, and data to learn, explore, and experiment with minimal cost in time or money. ClinFHIR is such a tool specifically designed for clinicians2. With more integrated and specific systems and more information available in real-time, “live” sharing of health data becomes the new norm, and FHIR resources are the ideal vehicle for digital health literacy. It is these characteristics of HL7 FHIR that allow it to function as infrastructure for interoperability and innovation, by connecting the dots from user experience to data exchange on the wire.

Standards for consent management [10] support the aim to increase security, trustworthiness and transparency of digital health services making individuals and organizations comfortable with sharing or donating data to the community. ISO/TC215, CEN/TC251, and HL7 with active participation from regulators like EMA and FDA, work on standards for the identification of medicines. The openMedicine3 project focused on the identification of medicinal products throughout their lifecycle with particular emphasis on cross-border ePrescription and eDispensation. Combining this information with the personal health data of the patient fuels innovation. For example, one can imagine strolling into a Pharmacy and consulting an app on over the counter medications most appropriate for them. We may also consider active personalized medication leaflets that adapt to their health and lifestyle offering alerts and enhancing medication compliance. Essential to the digital health compass is the use of reference clinical terminologies that contribute to higher data quality. SNOMED CT is active in this area with consistent efforts in user-interface terminologies to pave the way towards individualized digital health services.

Health on the Net code of Conduct

The Health on the Net code of conduct or HONcode [11] is a process metric to determine if the construction and maintenance of a website conform to approved standards of excellence. The HONcode is used to certify health websites with content respecting the HONcode criteria (see Figure 2). Compliance to the HONcode of conduct is reflected by displaying the HONcode seal. The HONcode contributes to the digital health compass by helping individuals make informed choices in accessing trustworthy content. Extensions of HONcode for health and wellness apps can be envisioned as a natural next step.

---

2 https://fhirblog.com/2016/11/06/clinfhir-profiling-walk-through/
3 www.openMedicine.eu and www.assessCT.eu
Health information technology standards assemble fragmented sources of health information, nurturing trust. Answering how different standards fit together and how joint products are governed and adapted to the changing needs of the community is essential. This is expressed in the vision of the eStandards project imagining: “...a global eHealth ecosystem where people receive timely safe and informed health care, anywhere around the globe and interoperability assets fuel creativity, entrepreneurship, and innovation, as digital health standards nurture large-scale eHealth deployments and enable co-creation with trusted dialogues on costs and plans that drive great expectations,” eStandards cooperates with the health informatics community on a roadmap for cooperative standards development, to form the core of the digital health compass.

### The case of patient summaries

Patient summary initiatives to make health information available to patients and families are supported by the EU Directive 2016/679/EU on Data Portability. The directive states the right of individuals to transfer their personal data from one electronic processing system to another, in a machine readable format. Combined with Directive 2011/14/EU on patients’ rights to crossborder healthcare and Directive 2013/37/EU on re-use of public sector information, patient summaries can be rethought as a tool for digital health innovation.

As part of the digital health compass, the patient summary helps individuals use their data and collect observations to develop the knowledge and confidence to select digital health tools that are right for them and engage productively in the digital transformation of the society. Patients, families and informal care givers join forces with the health team supported by research and development policies that advance digital health literacy. Health informatics supported by information technology standards and open application interfaces can serve as catalysts in the continuous improvement of data quality and the nurturing of trust relations in networks that transcend organizations, health systems and countries.

Trillium Bridge recommended that the patient summary includes at a minimum problems and procedures, medications and implantable devices, vaccinations, and allergies. Additional data to be included are labs, diagnostic images, and encounters. With FHIR resources one may retrieve specific sections of the patient summary or combine them in a clinical document. The low initial cost of working with FHIR opening up data sources traditionally behind organizational walls, helps shape the data sharing culture essential to construct the digital health compass.

### Figure 2– Principles Underlying the HONcode of Conduct.

Patient summaries can feed dashboards, the starting point in the search of health professionals for more detailed health information about a patient. Patient generated data can be summarized in this dashboard to assess progress towards achieving mutually agreed health goals supported by digital health literacy interventions. On the community level, patient summaries could help keep track of the health needs of the population and become an indispensable tool for evidence-based policy.

For the digital health compass, co-creation of patient summaries by patients, health professionals, and informal care givers comprises elements of digital health literacy, trust, and service provision. The key element of digital health literacy is understanding of health information for care, wellness, prevention, and engagement. To co-create in trust, data integrity of contributions from patients and providers and stewardship when sharing, interpreting, and complementing health information are essential. Finally, an element of service provision rooted in health experience and team play, advocates to liberate the data in the name of innovation and progress.

### Figure 3– Dimensions of the Digital Health Compass.

Personal experience is key in understanding the perceived impact on a person’s life, disease progression and expected outcome and impact of treatment options for individual patients in relation to their lifestyle choices. Tools for capturing, analysing, and relating all this data are becoming available with the person at the centre! First hand experts are the levers to adoption and they are not by definition technology driven. Frequently they are suffering from cognitive impairments and mutual trust is essential for them to willingly share the effects of the disease on their daily life and for technology experts to meet their needs. They are the ones who can tell us the real story behind the effects of this disease and its diagnosis, from their own experience with the disease. However, although patient needs should drive demand, frequently patients are in the back seat, while sustainability of the system, shortages in the workforce, fear of the unknown market regulation and traditional roles drive. Thus, we need to examine the perspective of health systems, workforce, consumers, and market guided by the core dimensions of the digital health compass: educate, enact, evaluate, empower, evolve, enable, and empower, shown in Figure 3.

### Perspective of health systems

The perspective of health systems centers on cost containment, performance, and quality care. Digital health services routed in a data culture can help unlock productivity in health care. Platforms inspired by the sharing economy can bring tangible improvements in administrative automation, networked knowledge, and resource orchestration for higher productivity [12]. In 2015, Uber Health was able to deliver 2000 flu shots in 35 cities over 4 hours. However, countries in Europe still lag behind in patient empowerment and appreciation of network effects [13]. Collecting and analyzing data, health systems can measure the degree to which people are confident when nav-
gating health services online, booking appointments or accessing their health information. Health systems may also share resources with other health systems to increase productivity.

Patient summary services linked to productivity and incentives can engage patients in their health goals in partnerships with the health team. Establishing incentives for high quality recording or assembly of patient summary data can directly improve data insights guiding interventions with direct impact on increased productivity, and patient satisfaction. Note that the concept of health system navigators is not new. It was first introduced by Harold Freeman in 1990. Assisted by medical students, patients are able to navigate the logistical, emotional, and frequently cultural barriers of receiving care. Patients are assisting in assessing the situation and choices, articulate objectives, evaluate alternatives and reach decisions. In the end, healthcare is analog and human touch is paramount. Digital health tools can help fill the intention gap!

**Perspective of health providers and the workforce**

From the perspective of health providers and the workforce, maintaining cutting edge competences is essential. The rapidly unfolding technological environment leaves health professionals perplexed and confused in front of well-informed or arrogant know-all patients that need to be “de-googled”. On the other hand, personalized treatment demands a partnership with the patient. For the workforce, the digital health compass needs to preserve the balance of roles in new quality relationships catalyzed by technology. Human relationships and empathy are challenged by complex knowledge-based remote cooperation. Self-care or care between care make physical encounters rare and precious.

**Perspective of the digital health market**

The digital health market is seeking opportunities to match demand and supply of digital health services. Established practices and a long standing fee for service reimbursement model of care, hinder adoption of innovation. Consider the case of the personal health record (PHR) as a digital organizer of personal health information. PHRs provide treatment support with self-management options. They facilitate sharing and exchange of health data with healthcare providers, suggest healthy lifestyle options, and track exercise, health and fitness. However, PHR adoption is not wide-spread and willingness to pay is low. Healthcare systems and government spending drive the market.

A recent study in 25 countries and 6 continents, revealed that most PHRs never go beyond the pilot stage of 100 -1000 subscribers. The study notes that some government strategies have succeeded in scaling up health information exchange between citizens and the health system. In contrast, the lifestyle focus of tech companies in the consumer market does not contribute to PHR initiatives across countries. Experience, preferences for engagement, health coaching, and use of digital health information are at an early stage. The promise of data fails to deliver market value. Exceptions to this rule marking future trends are patient advocacy groups that sponsor clinical trials and mediate transfer of clinical results to routine patient care.

The eStandards project identified several gaps to be bridged by cooperative standards development including creating a reliable mix of patient and provider generated health data. Additional gaps identified were bridging health professional guidelines with clinical information models and terminology initiatives, establishing regulatory clarity, and attending to localization and adaptation of user requirements with a clear connection to procurement. Lastly, eStandards highlighted the need for clear governance and maintenance of standards sets supported by open tools and data to leverage different speeds and cycles in sharing and integrated fragmented data. The bimodal practice of managing separate but coherent styles of work leveraging predictability and exploration is promising for diffusing health innovation matching technology supply with patient demand.

**Perspectives of citizens and informal care givers**

Citizens and households need to manage health information. Their methods vary in sophistication, time relevance, robustness, and creativity. Health information managers employ idiosyncratic tools and strategies to keep track of health data over time. Active involvement in health decisions is frequently expected and needed, as they navigate health systems to the best of their abilities seeking the best options. The first step to moving online is accessing and acting upon personal health information stored in health systems that are called to play a critical role in digital health literacy of both patients and the workforce.

Patients are best placed to have the most complete picture by being present in every encounter in a personal capacity. However, health confidence, health status, personal wellbeing, etc., combined with preferences for engagement, digital confidence, skills and capabilities including language, length, reading age, etc. affect their ability to use digital health tools and resources. Standards and quality labels reflect capabilities to connect and assess resources. Citizens make deliberate choices of sharing health related information, choosing to actively solicit, share or protect information pertinent to their conditions or health problem [14]. Patients want access to their health data, and appreciate opportunities to do so. Meanwhile, more and more, they share their experiences in online social networks and trust the feedback received.

With the Internet of Things, mHealth tools and apps add to the body of tools to manage data from the environment. IoT offers insights to the activities in the home, and the plethora of information sources and health related activities citizen engage in and perform [15]. Robust strategies to differentiate and handle health information emerge:

- **Just-in-time**, i.e. information and/or artifacts are with me at most times
- **Just-at-hand**, i.e. information and/or artifacts are visible or stored in readily accessible, highly familiar locations in a household
- **Just-in-case**, i.e. information and/or artifacts, either personal health files or general health information resources, are kept away, but are easily retrievable
- **Just-because**, i.e. information and/or artifacts of temporal relevance, kept in the household until storage strategy is assigned [16].

These human approaches to managing health information reflect strategies for maintaining confidentiality and privacy, bridge provider-generated and patient-generated data, and reduce fragmentation of health data providing support in the "care-between-care" period guiding inter-visit care actions [17].

**Call for action: My data, my decision, our ePower**

In this multifaceted health information ecosystem, our call for action is paramount. Adoption of innovations proceeds at the

---

5 http://www.hpfreemanpni.org/
speed of trust and issues of trust apply especially to the perspective of citizen and health providers. In our call for action we see collaboration and co-creation and where both digital health literate citizens and the health team see the relevance and value of accurate patient summaries. This implies that citizens become able and empowered to identify, appraise, and use their health information purposefully, and transform it into specific, trusted, and actionable knowledge applicable to the health reality at hand. Thus, health information should be relevant, regardless of source as health professionals or the citizen self are aligned to make sense of it in a sort of trialability that fosters large scale adoption, sharing and use [18].

My data
Individual knowledge and capability to manage one’s health, to get appropriate help when needed and engage in shared decision-making are part of Health literacy. It emphasizes motivation, knowledge and competencies to access, understand, appraise and apply health information to all aspects of citizens’ health judgments and decisions in everyday life [19]. Adding on the ability to appreciate and use productively digital health tools can be reflected in using patient summaries as the passport to this health journey.

My decision
Information relevant for the specific circumstances will help assemble information to participate in tomorrow’s care. We expect more productive interactions and co-creation where the personal dimension; socio-demographic factors, Health and Digital Health Literacy span the full spectrum of “worried well” and the “really ill”. Digital literacy boosts skills and capabilities to participate, and advance technology readiness. Marketing recognizes Self Achievers, Priority Jugglers, Direction Takers, Balance Seekers, and Willful Endurers. Taking into account the behavioral profile of an individual can help calibrate their compass. Moreover, the Health Confidence Score (HCS) is a short generic measure of a person’s confidence to engage fully in their health and care measuring knowledge, self-management, access, and propensity to shared decision-making [20]. These are essential elements of advancing digital health literacy in a process that respects individuals allowing freedom of choice on when, how, and what digital health tools to use.

Our ePower
Empowering the citizens (patients, families and carers) to support a continuum of care across a range of services can relieve pressure on governments to provide more cost-effective and efficient health services improving health outcomes and encouraging citizens to manage their healthy life course. Beyond socio-demographic aspects that challenge adoption of digital health technology and a culture of sharing data that could drive routine evidence-based decision making.

Conclusion
The vision of the digital health compass as a navigation instrument that allows us to make sense of digital health innovations has been presented using patient summaries as an illustrative example. We argued that eHealth literate citizens are empowered and can make better choices. With increased digital health literacy, citizen can identify, appraise and use more health information resources, and transform them into trusted, actionable knowledge applicable to the situation at hand. Understanding one’s health data is a foundation for empowerment. Co-creation and participatory design facilitate the design of information visualizations that are understandable and actionable, promoting active engagement. Cooperative use of standards is the key to creating a trusted infrastructure for innovation, since innovation travels at the speed of trust.

Electronic Health Records in the Cloud: Improving Primary Health Care Delivery in South Africa

Liezel Cilliers\textsuperscript{a}, Graham Wright\textsuperscript{b}

\textsuperscript{a} Department of Information Systems, University of Fort Hare, East London, Eastern Cape, South Africa
\textsuperscript{b}Department of Health Sciences, University of Fort Hare, East London, Eastern Cape, South Africa

Abstract

In South Africa, the recording of health data is done manually in a paper-based file, while attempts to digitize healthcare records have had limited success. In many countries, Electronic Health Records (EHRs) has developed in silos, with little or no integration between different operational systems. Literature has provided evidence that the cloud can be used to 'leapfrog' some of these implementation issues, but the adoption of this technology in the public health care sector has been very limited. This paper aims to identify the major reasons why the cloud has not been used to implement EHRs for the South African public health care system, and to provide recommendations of how to overcome these challenges. From the literature, it is clear that there are technology, environmental and organisational challenges affecting the implementation of EHRs in the cloud. Four recommendations are provided that can be used by the National Department of Health to implement EHRs making use of the cloud.

Keywords:
Electronic health records; cloud computing; primary health care

Introduction

The primary health care system in South Africa is facing many challenges. These difficulties include the high disease burden consisting of infectious and non-communicable diseases, persisting social disparities, and a lack of qualified health staff. South Africa’s population is estimated in approximately 54 million people, while 54% of this population lives below the poverty line [1]. It has been reported that in South Africa 84% of the population cannot afford a medical aid, and thus making use of the public health care sector, which only employs 20% of the health care workers in the country [2].

The shortage of primary health care facilities is most acute in the rural areas of the country. Patients living in these areas often travel far distances at considerable cost to access health care services [3]. When the primary care facility cannot treat the patient, they are referred to the next tier in the health care system, which is the secondary level district hospital, or the last tier, that provides tertiary services, and these are often located far away in the city. Thus, patients can have many health care providers throughout the public health care system, all of which will have their own health care records for the particular patient. If the file is misplaced at the health care facility, a new file must be opened and all the medical history before the event is lost. This means that patients often have multiple files at a single facility. To exacerbate the situation, if the patient move to another region or province, their health record will remain behind, and their health care record will have to be started anew [4].

The most common method to record health care data in South Africa is a manual, paper-based health records. The National Department of Health (NDoH) has made attempts in the past to implement an electronic health record system to improve the continuity of care, but these efforts were fragmented at best resulting in interoperability issues between the various systems being used [4]. While the cloud can overcome the problem of interoperability as one system can be made available to every health care facility in South Africa, the adoption of the cloud in the public health care sector in the country has been slow. Some of the reasons provided for the slow adoption of the cloud are security concerns, trust of the cloud, and compliance to legislation [5]. The aim of this paper is two-fold: First, the challenges why the cloud has not been used to implement EHRs in South Africa will be investigated, and second, recommendations to overcome these obstacles will be provided. The next section will discuss the definition and use of electronic health records in the South African public health care system.

Electronic Health Records

According to the Health Information and Management System Society [6], although the terms EHRs and electronic medical record (EMR) are often used interchangeably, they actually refer to separate concepts. An EMR is a local, stand-alone health information system that allows for the storage, retrieval and modification of health records. The EMR refers to the legal patient record that is created in the health care environment, by the health care worker, and becomes the data source for the EHR.

The EHR is an electronic version of the patient's medical history, which includes clinical data and history, progress notes, medications, vital signs, past medical history, immunisations, laboratory data, radiology reports, and administrative data. The EHR can be shared among health care providers at the same hospital and across different health care settings through an information system that is connected via a network, e.g. the cloud [3, 5]. However, many patients have privacy concerns when their medical data is stored in an EHR.

Privacy in the context of EHRs means that the patient must retain control of their own information even if it is ‘owned’ by another party, such as the hospital. This control extends to whom is authorized to access a copy of the data, e.g. where billing records are shared with the medical aid company, or different health care workers are authorized to view the EHR [7]. The EHR must be delivered in an environment in which patients have absolute confidence that their privacy will be protected and that the confidentiality, integrity and availability of the information stored in EHR will be assured [3]. The next section will discuss cloud computing in the healthcare sector.
Cloud Computing

Cloud computing has the potential to make health care more efficient and effective. Storage of medical data, processing capabilities of the EHRs, and bandwidth necessary to share the records are centralised to become more efficient. However, while the cloud has been adopted in many industries, the health care sector has been slow to make use of cloud-based solutions [5, 8].

The cloud makes use of internet connectivity and a standard web browser to allow the health care worker to access the EHR. An advantage of the cloud is that the health care organisation do not have to develop or maintain the hardware and software infrastructure necessary for the EHRs, but simply make use of the cloud services and deployment models that best suit their specific operational and technical needs [5].

There are three service models that are applicable to the cloud in the health care sector. The first is Infrastructure as a Service (IaaS) that allows health care workers to provision processing, storage, network, and other resources in which they can deploy and run arbitrary software, such as operating systems and EHRs applications. This means that the health care organisation does not have to manage their own infrastructure and can add computing processing power and storage capacity as the need arise. The main benefit of IaaS is the fast deployment of applications and the improved agility of information technology services within the organisation. However, the NDoH do not have their own EHRs application in place at present. Therefore, this option does not seem appropriate. The second service model is the Platform as a Service (PaaS) that allows for the quick and efficient development of health applications that can be hosted in the cloud. This environment allows the NDoH to build applications with no capital expenditure on infrastructure, as the service provider is responsible for the maintenance and control of the underlying cloud infrastructure. The NDoH could use this model to build their own EHRs, but with the lack of information technology skills in the public health care sector in South Africa, this solution does not seem viable. Third, service providers make use of a Software as a Service (SaaS) model to provide access to applications and software remotely through a web-based service. The cost of accessing these services is typically less than paying for licensed applications, as the health care organisation only pay for the actual time they use the application, and there are no hardware layout costs. The service provider is also responsible for the installation, set-up and maintenance of the services they provide. In this model, the service provider would provide the application for the EHRs, and the NDoH would pay for the usage thereof [9; 10]. This option would also overcome the problem of integration between the various health care facilities, as a single program will serve the South African public health care system.

There are four cloud deployment models: private cloud, community cloud, public cloud, and hybrid cloud. The private cloud is hosted and operated by one organisation, while the community cloud allows several organisations, normally with a common goal to share the infrastructure. The public cloud is owned by an organisation that sells cloud services to the general public or a large industry group. The last deployment model, the hybrid cloud, is a composition of two or more clouds that remain unique entities but are bound together by proprietary technology [10]. The private cloud could be used by one organisation, such as a medical aid company, to provide EHRs to their clients, but this system would not be integrable with other systems outside the company’s sphere. A company such as Google that provides EHR services to the public would make use of a public cloud, but there are privacy and security concerns with such a deployment model. The model that is best suited to EHRs, therefore, seem to be a community cloud, as health care providers share a common goal – to provide more efficient and effective access to the medical data of the patient [9, 10].

The benefits of cloud computing to provide EHRs to the public health care service in South Africa can be derived from the discussion above as well as the following [11]:

1. Reduced cost to the NDoH, as they do not have to maintain the information technology infrastructure.
2. The cloud is available on demand to the health care worker and can be accessed from any location.
3. The resource pooling of physical and virtual resources allows for the most efficient use of the technology.
4. The cloud provides flexibility to the NDoH, as it can be easily scaled according to the need and demand of the health care facility.
5. The cloud provides usage metrics that can help the NDoH in the decision-making process for future technology usage and planning. These metrics can also contribute to the sustainability of the EHRs that is provided.

Electronic Health Records in South Africa

HealthID

Discovery Medical Aid is providing an EHR to their clients called Health ID. This EHR is the first of its kind in South Africa according to Discovery. The purpose of HealthID is to collate the medical data and details of all hospital visits, including scripts for medicines, blood tests and health indicators. The patient must provide written consent for each of their health care workers they visit to access their HealthID in order to protect their privacy. The consent can be provided before the appointment or during the visit by accessing the patient’s Health ID profile on the Discovery website [12].

The purpose of Health ID is to reduce the administrative burden on the health care worker, as they have access to the full medical history of the patient regardless of where their previous visits took place, as well as the health benefits of the patient. The real-time access allows the health care worker to apply and receive approval for chronic medication and to identify what medication the patient is currently taking, which is especially useful for elderly patients that may not be able to remember [12].

Google Health

This product was available in South Africa through the Google platform from 2008-2012. Google Health provided the patient with an opportunity to manage their own health information, although the EHR could not be shared with the health care worker. Unfortunately, Google Health was not adopted by the general public and achieved only limited use; hence, it was discontinued in 2012. While the system quality of Google Health was found to be appropriate, the system was perceived to be high risk resulting in low trust among users. The lack of awareness among users about the benefits of EHRs contributed to the lack of trust, as well as the failure of health care workers to recommend the product as a useful tool to collect health information. The functionality of Google Health was also limited. The user could not make the application available to their health care provider, but only use it to manage their own health information. Klein suggested that patients were not ready to manage their own health data in 2008, which contributed to the lack of adoption among users [13].

Nompiilo service

Vodacom in partnership with local Non-Governmental Organizations and the NDoH launched an application which provided end-to-end monitoring and evaluation for local
community workers in 2009. When these workers visit the patients in the community, they can upload patient information directly to the system making use of their smartphones. Each patient is assigned a unique 2D barcode that can be used to identify them on the system. Nompilo then shows the health care worker what information needs to be collected from that particular patient. Typical information collected include personal, administrative, and physiological data to support the treatment plan. Current and historical patient information can also be viewed remotely, in real time, by the health care worker [14].

**Electronic health record systems in the public health care sector**

The South African NDoH has also started to implement EHR systems in their public health care sector. Currently, 5 out of the 9 provinces in South Africa have some form of EHR system operational in public hospitals. In the KwaZulu-Natal province, some hospitals use the Medicom or Meditech EHR system, while in the Western Cape province a few hospitals use the Unicare or Clinicom EHR systems. Hospitals in the Limpopo province also use the Unicare or Medicom EHR systems [15]. The implementation of different EHR systems from various vendors presents a challenge, as these systems are built with different underlying database architectures; and therefore, often fail to communicate and share information amongst each other. Also, while these systems have been implemented in some areas, the majority of the public health centres in South Africa still make use of a paper-based filing system [16].

**Methods**

The research was exploratory in nature, and reviewed literature from previous studies, e.g. articles published in academic journals, books (both print and electronic formats), conference proceedings and websites relative to this study. Electronic databases such as ACM Digital Library, Sage Online Journals, Science Direct, Springer Link and Sabinet Reference were used to find the literature. Research keywords such as ‘electronic health record’, ‘electronic medical record’, ‘cloud’ and ‘primary health care’ were used as search terms. The reference lists within articles previously identified were also examined to yield additional literature. Inductive reasoning was applied to analyze the literature making use of a thematic content approach. The results of the analysis are discussed in the next section.

**Discussion**

Duhaime [17] provided the following list of generic barriers that must be considered when cloud computing is implemented in any organisation (Figure 1). These barriers are discussed in the context of EHRs below.

![Figure 1 - Generic barriers to the implementation of cloud computing (adapted from Mathew, 2012 [18])](image)

**Scale, Cost and Reliability**

Performance concerns about the cloud are often based on the scale, availability and the dispersal of the cloud [18]. The technology needs to be reliable and accessible to be useful to the health care worker. In Africa, the primary barriers to the implementation of the cloud include unreliable electricity supply, poor internet connectivity, and limited bandwidth. Internet penetration in Africa is the lowest of all the developing world regions, with only 0.3% fixed broadband penetration on the continent, and internet penetration at 16.3% [19]. As an internet connection is needed to access the information in the cloud, these factors will influence the reliability of the EHRs. There are several different factors that will determine the cost of the technology, especially if SaaS service model is used. These include the amount of storage required, network services, scheduling, service level agreements, optimal location of data centres and software components, efficient SQL query processing, architecture and process improvement.

**Lock In and Agility**

One of the advantages of the cloud is the agility that it provides in regards to capacity, storage and demand. When the NDoH decides to make use of one vendor, they become ‘locked-in’, as they are then obliged to deal only with that company and their products. If there is a need to migrate away from that vendor, then a significant cost will be incurred. At the present moment, the EHR systems that are used within and across provinces are not integratable [16]. The patient data in these legacy systems will have to be imported into the new EHRs to ensure continuity of care. This may be a problem as the maturity of the technology in South Africa is still low, which means that the industry is not regulated and standardisation between products are non-existent [3].

**Change Management**

Cloud computing is a new technology that is changing the traditional way of managing health care information in the public health sector. The lack of knowledge about the cloud is one of the reasons the NDoH is reluctant to migrate to the cloud because health care staff and patients are not aware of the cloud’s purpose [20]. Due to this lack of understanding, staff may fear that they will become redundant and patients may have misgivings about the safety and privacy of their information and resist the use of the new technology [4].

The failed Google Health application was a prime example of how the relationship between knowledge of the cloud and trust in the cloud is essential for the adoption of the technology. This is because knowledge of the technology is likely to enhance the levels of trust of the user, ensuring it’s continued used (Google). Therefore, the NDoH must conduct a needs analysis of their employees’ and patients’ knowledge of cloud computing before the technology is implemented to manage patient records [10].

**Lack of Control**

EHRs have to manage sensitive patient information. Comninos [21] found that one of the main reasons why patients and healthcare workers are reluctant to make use of the cloud is concerns about third-party cloud providers that must store or process this sensitive information. Also, connectivity issues are also a concern, as the health care worker can only access information if they are connected to the internet. The lack of
transparency in the cloud is contributing to the control concerns of EHRs. The user is expected to upload their health care information without any knowledge regarding the security measures or controls in place in the cloud. Often, the user does not even know where the information is located, making litigation difficult is something should go wrong [20]

**Security**

EHRs store and process large databases of sensitive patient information. Many patients have expressed privacy and security concerns if this data is transferred to third party providers of cloud services as the cloud is seen as inherently not secure [20]. The main reason for this perception is that the security in the cloud is intangible and less visible, which creates a concern whether information is stored securely. Security concerns include the altering or loss of sensitive data in the cloud and the unauthorized use of the data by cloud providers [18].

**Discussion**

In the previous section, the generic barriers for the utilization of the cloud to provide sustainable EHRs services in the public health care service of South Africa were discussed. In summary, the following critical areas were identified:

- Technology: Vendor lock-in; agility and maturity of products available; standardization, reliability and availability of technology; cost of making use of the cloud;
- Organization: Change management including trust; adoption and awareness of the cloud; and
- Environment: Security and privacy concerns.

The following are recommendations that were developed to overcome these critical areas and improve the implementation of EHRs in the cloud. The first recommendation is to provide education to improve the level of awareness about and trust in the cloud, and the benefits it can provide to EHRs. One of the reasons why Google Health failed was because it did not engage with the users showing why EHRs was beneficial to manage their health care, and how cloud computing could help them to manage their EHR. The recommendation is thus twofold as both health care workers and patients need to be educated about the advantages and potential risks of making use of the cloud. With this knowledge gain, it should increase user acceptance and utilization of the technology.

The second recommendation is for the government to provide best practices for both EHRs and cloud computing within a legislative framework. EHRs are already included in the E-Health Strategy for South Africa, but the National Department of Health must also provide a national integrated plan for the implementation of a national EHR system. Best practices, such as to how any service can be implemented making use of cloud computing will also address the problem of vendor lock-in and legacy systems that are not integrable with the national system. Legislation and policies need to be put in place to ensure compliance of the technology with international standards.

The third recommendation is to improve the transparency of the cloud to address the privacy and security concerns. Legislation that provides a proper legal framework, such as the Protection of Personal Information Act, will guide the user, health care worker and cloud provider as to what their rights and responsibilities are. This improves the control on the part of the user and health care workers.

Security controls in place, to protect data, should be provided by third-party cloud providers to assure users that their data is securely stored. Security controls will further improve the transparency of the cloud and provide peace of mind to the patient that the privacy of their sensitive information will be protected. The recommended security requirements include certification, where developers open their cloud applications to security specialists that provide certification for security. Certification will certainly improve the trust of the user in the cloud-based EHRs [22].

- Identification and Authentication: all accounts should incorporate usernames and passwords to verify the user on the cloud, and provide an audit trail of access to that specific EHR;
- Authorization: The challenge is to provide the right information to the right person, while limiting the access privileges of the user. Patients should be able to grant privileges to health care workers, while the functionality of the EHR should be restrictive to who can add or modify information. Patients may not realize why it is important not to change test or laboratory scores. Each user will have to be allocated manually with security clearance to ensure limitation of access to different files;
- Integrity and Confidentiality: encryption techniques should be used to protect sensitive data of the patient;
- Non-repudiation: health care workers and patients must have access to the data at all times for EHRs to be useful. Techniques including digital signatures, timestamps and confirmation receipt services can be deployed to achieve non-repudiation; and
- Availability: It means that the data will be available, accessible and obtainable at all times on the health cloud, while time-outs must be used to restrict access of unauthorized persons if the user forgets to log out of the application.

The fourth recommendation is to address technology problems that may affect the cloud specifically. Cloud computing is still a relatively new technology with limited use in the health sector. Specific technology factors that must be considered include the reliability, cost and availability of the technology. These are important because access to health data must be reliable, if the EHRs is to be of any use. The total cost of migrating to the cloud will decrease, as more deployment options become available. The cost of bandwidth, which is very expensive and limited in South Africa, must also be decreased to make this a viable technology. In developing countries, especially where IT infrastructure is poorly developed, cloud computing makes use of existing internet connections without requiring more infrastructure or financial investments.

**Conclusion**

This paper provides an overview of the current use of EHRs in South Africa. This includes systems available to the individual patient and the health care worker to manage medical data, and illustrates that EHRs are slowly making inroads in the health care sector. Reasons why the cloud has not been used to provide EHRs in the public health sector of South Africa were divided into the organizational, environmental and technology categories. Four recommendations were provided to how to overcome these challenges that can be used by the NDoH to implement cloud-based EHRs.

Future work would include testing these recommendations making use of an expert review to refine them. It would be useful to investigate the extent of EHRs implementation in the public health care sector and compare these results with the private health care sector. An examination of the adoption of
HealthID among patients belonging to the Discovery medical aid could also provide valuable insight.

Decision-Tree Model for Support of Health Policy Choices Based on Pneumococcal Conjugate Vaccine (PCV) Program Outcomes

Abstract

Pneumococcal Conjugate Vaccine (PCV) has the potential to save lives in low-income countries. We have developed a computational model and web-based decision support software for comparing cost-benefit tradeoffs from alternative PCV program designs, considering their direct and indirect effects on early childhood populations in resource-poor settings. This supports policy-makers in estimating potential health outcomes and cost-effectiveness of different vaccination program strategies for a wide range of population coverage and vaccine effectiveness assumptions.

Keywords:
Health Policy; Conjugate Vaccines; Decision Support

Introduction

Despite its potential to significantly reduce pneumococcal disease – a major cause of death in under-five year olds in resource-poor regions of the world, the high price of Pneumococcal Conjugate Vaccine (PCV) has deterred introduction in many of the low- and middle-income countries where such prevention is needed the most. For policy makers in these countries, often operating in resource-constrained environments, the relative costs and benefits associated with introduction of a vaccination program as a one-time effort vs. one with catch-up for children who may have missed the first opportunity and may require catch-up vaccination, is something that needs to be estimated rapidly and efficiently. Traditional epidemiological models require detailed estimation and computation – a review of different modeling approaches can be found in the literature [1]. For practical purposes of providing decision-support for making policy recommendations, an incremental cost-effectiveness model, such as that developed in the TRIVAC system [2] as a spreadsheet software program, has been shown to be most effective to obtain estimates for policy decisions. It uses parameters, such as demography, disease burden, vaccine costs, vaccine coverage, vaccine efficacy, health service utilization, and costs. With results of this kind of model in mind, we have developed an interactive, portable web-based health policy analysis software tool [3] that is computationally efficient, and allows calculations and comparisons with alternative assumptions about population characteristics and vaccination program details from a wide range of investigations [4 – 11] about the effects of pneumonia vaccination, which we have designed for estimating impact of the introduction of vaccination programs to counter infant pneumonia in countries with limited resources.

Methods

Our model is based on combined results from three international efforts to assess the burden of pneumococcal disease and to develop standards for assessing cost-effectiveness of preventive vaccination strategies: a) WHO-Hib Pneumococcal Global Disease Burden Project (GDB) for children under 5 [2]; b) Global Serotype Project (GSP) for regional proportions of disease-causing pneumococcal isolates covered by PCVs; and c) WHO CHOICE for country-level medical costs of disease management and treatments.

Decision Tree Model Structure and Parameters

The model divides a birth cohort into subgroups of patients who experience pneumococcal pneumonia, pneumococcal meningitis, and non-pneumonia/non-meningitis invasive pneumococcal disease (IPD), with each subgroup distributed over possible outcomes of death, disability (deafness, seizures, etc.) or survival without disability. A decision tree structure is used with contingent events appearing as branching sub-trees, and possible outcome states (terminal nodes) associated with utilities, or Disability Adjusted Life Years (DALYs).

Branches of the tree, following round nodes, may occur with given probabilities which are used in this model to represent vaccination rate, serotype coverage, or the chances of mortality and morbidities, etc. Each branch of the tree may also be associated with costs, which accumulate downstream. The basic pneumococcal vaccination policy model, illustrated in Figure 1, involves a decision between two scenarios: Vaccination Program and No Vaccination. In the vaccination scenario, a given proportion of the population is vaccinated, which in turn can prevent a proportion of the serotypes of disease. Probabilities of events vary for each subgroup of the population in each scenario, which can be computed based on the prevalence of each event and the vaccine efficacy, if any, for those events. Children with disease have a certain chance
of death, and those who survive may have an amount of disability over the course of their remaining life expectancy.

**Disease Incidence and Case Fatality Ratios**

The probabilities of events are based on data available from the GDB project, including disease incidence (per 100,000 infants) for each country, estimates for case fatality rates, the number of events, and deaths observed in children under 5, that were subject to a rigorous meta-analysis. GDB incidence reflecting a 5-year cohort is converted to a probability of disease in a single birth cohort.

Case fatality ratios are also derived from the GDB data; however, since the incidence values for non-pneumonia/non-meningitis IPD reported in the GDB are based on acute disease, we had to explicitly re-compute the incidence based on the underlying values for all disease. For this reason, we also accept the observed number of events and deaths as inputs, as an alternative to the case fatality ratio, which is provided if available.

**Vaccine Serotype Coverage and Efficacy**

In the vaccination scenario, the probabilities of events for vaccinated children reflect the impact of vaccine efficacy for the covered serotypes. This is further complicated by modelling the varying efficacy in presence or absence of HIV, so resulting efficacy can be expressed by the formula:

\[
\text{Effective Efficacy} = \text{Vaccination Coverage} \times \text{Serotype Coverage} \times \left( \frac{(\text{Prevalence of HIV}) \times (\text{Efficacy with HIV}) + (1 - \text{Prevalence of HIV}) \times (\text{Efficacy without HIV})}{2} \right)
\]

We used 2006 WHO/ UNICEF estimates of the proportion of children receiving three doses of diphtheria-pertussis-tetanus vaccine (DTP3) to estimate the proportion of children likely to receive three doses of pneumococcal conjugate vaccine when introduced into a childhood immunization schedule. Serotype coverage estimates were initially estimated as the proportion of disease-causing pneumococcal isolates that are serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F in children under-five. These serotype coverage estimates were taken from regional estimates from the Global Serotype Project [GSP Summary Report 2007]. The regional groupings used were Africa, Asia, Europe, Latin America, the Caribbean, North America, and Oceania. The online edition of the model was updated to use estimates for a 10-valent vaccine (1, 4, 5, 6B, 7F, 9V, 14, 18C, 19F, 23F) computed from the meta-estimates that appear in GAVI's Pneumococcal ADIP TPP Codebook.

**Measure of Effectiveness: Disability adjusted life years (DALY)**

Disability Adjusted Life Year or DALY is a burden of disease measure used to assess the relative utility of each possible health outcome. The DALY combines in one measure the time lived with disability and the time lost due to premature mortality. One DALY can be thought of as one lost year of 'healthy' life. It is calculated based on the age at which disease occurs, the life expectancy at the time of disease occurs, and the expected duration of disability. It is weighted to account for the years of life during which an individual is anticipated to be most economically productive and is discounted to present value. Years of Life Lost (YLLs) is computed as a function of a discount rate (r), an age-weighting parameter, an age-weighting modulation factor, a constant, and the life expectancy at the age of onset of disability. Standard values from the WHO GBD project are used as defaults, but can be adjusted by the user. When calculating disability-adjusted life years attributable to acute illness or non-fatal permanent sequelae, it is assumed that time lived with acute illness or with a sequelae is valued less than time lived in perfect health. Disability weights are used to represent the preference for time lived in perfect health relative to time lived with acute illness or with a permanent sequelae. DALYs attributable to acute illness or permanent sequelae are termed Years Lived with Disability (YLDs) and are calculated using the formula:

\[
\text{YLD}s_{[r,K,beta]} = \text{Disability Weight} \times \text{YLLs}_{[r,K,beta]}
\]

where the disability weights for each sequelae are also the standard values from the WHO GBD project. 

The summary metric the model aims to calculate is the incremental cost-effectiveness ratio. This is:

\[
\text{Net costs/ Net health benefits} = \frac{(\text{Vaccine-related costs} - \text{Averted disease costs})}{\text{Disability-adjusted life years averted}}
\]

Data from diverse sources are drawn together in calculating each of the three terms. The quality of the completed model is dependent on the quality of the data input into the model. The development team has striven to identify the highest quality sources of international data for use in the pre-populated model. If modifying these pre-populated inputs, we encourage users to develop a quality assurance process, to consider accuracy, precision, and generalizability of estimates prior to incorporation into the model.

**The Web-Based Interface and Software Design**

The model is embedded in a general purpose decision support framework consisting of a series of dynamic web pages that provide complete documentation of all input parameters to the model, and a mechanism to allow policy makers to enter new values within reasonable limits. It is operable on any standards-compliant web browser. For convenience, pre-populated values are available for each country, for which GAVI eligible countries can be selected on a map. The input data values for the model are presented in series of pages, arranged as a “tabbed” notebook, in which they can be examined or modified. Most entries, technical term, and sources of baseline data values, are documented by hyperlinks to Glossary, Frequently Asked Questions, and References pages. An example interface page is shown in Figure 2.
Software features for efficiency and portability include:

- Use of standard HTML pages, making the decision support framework platform-independent and operable on any computer with a web browser,
- The interface and evaluable model can be accessed in areas without internet access via CD-ROM,
- Ability of users to perform customized sensitivity analysis,
- Can import easy-to-use Excel spreadsheets that contain all the variables and values for specific countries into the model, and
- Provides an efficient, low-cost method for geographically dispersed analysts to project and compare disease burden and cost outcomes for vaccination strategies of interest for specific countries or regions utilizing the best available data.

Results

Key model outputs can be prepared by country, by year, or cumulative over ten years, and include:

- Pneumonia, meningitis, and NP-NM IPD Cases/deaths and cases/deaths averted,
- YLDs, YLLs, total DALYs, and DALYs averted,
- Vaccine program costs, disease treatment costs and net costs, and
- Average cost-effectiveness of a vaccination program (each option compared to no vaccine) and incremental cost-effectiveness (options ranked and compared to next best option) over the years of a program.

A screenshot of results from running the model for the country of Vietnam are shown below in Figure 3, highlighting the cumulative disease burdens after 10 years of a vaccination program, and the reduction in cases of pneumonia and expected deaths contrasting introducing a newborn vaccination program only vs. alternatives of programs with catch-up from enrolling children under 1 of age or under 2 years of age.

It can be seen that the results for a catch-up program that includes all children under 2 years of age will be the most effective in reducing total numbers of cases and numbers of deaths. We have run the program for a large number of data sets from many countries which are resource-poor or emerging from this category, such as in the case of Vietnam. Results summarizing the decreases in % of cases and deaths for the most vaccine vs. the most effective program of under 2 catch-up are shown in Table 1. The dramatic decrease in mortality and disability for the two options is illustrated in Table 2. And, the impact on costs for hospitalization and treatment of disabilities is just as dramatic as shown in Table 3 on economic burden.

The above is just one example out of many showing the results of the model, for which assumptions such as protective herd effects or serotype replacement can be adjusted. We next show – in Figure 4 – a graph of how the percentage of cases averted and the percentage deaths averted will show considerable improvement over the early years of the vaccine program, and then level-off towards the end of a ten year period as most children in a population have been reached by the program. Figure 6 shows the dramatic effect of decreased numbers of expected cases of mental retardation from meningitis that could be averted by the introduction of the PCV immunization as administered to newborns, or with catch-up programs for immunizing children under-1 and under-2 for two levels of assumed efficacy.
Discussion

The results reported here show how the efficient and effective model of reductions in disease burden and costs for a pneumococcal conjugate vaccination program can play out over the course of the program. The tradeoffs between different types of assumptions about population coverage and vaccine effectiveness are the most important practical results which can be derived from these types of analyses in order to assist policy makers in choices of program strategy to adopt given the resource constraints that they face.

Conclusion

The description of the model and implementation with results for an example country showed how the impact of PVC programs with catch-up for children up to 2 years of age can be considerable, with cases and deaths averted amounting to over 70 to 80% of those that would occur without a vaccination program. The portability, ease of changing parameters to carry out sensitivity analyses, and ease of use of the software we have described show that it represents a practical software tool to support policy-makers in testing the possible outcomes of their choices of vaccination program strategy.

Acknowledgments

The authors thank their collaborators Dr. Frank Sonnenberg and, with especial gratitude Dr. C. Greg Hagerty, who was instrumental in producing the first implementation of this system and has since passed away, for their work on the earlier version of the model and software.

Enabling Patient Control of Personal Electronic Health Records Through Distributed Ledger Technology

James Cunningham and John Ainsworth

The Health eResearch Centre and The Farr Institute, Division of Informatics, Imaging and Data Sciences, School of Health Sciences, Faculty of Biology, Medicine and Health, The University of Manchester

Abstract

The rise of distributed ledger technology, initiated and exemplified by the Bitcoin blockchain, is having an increasing impact on information technology environments in which there is an emphasis on trust and security. Management of electronic health records, where both conformation to legislative regulations and maintenance of public trust are paramount, is an area where the impact of these new technologies may be particularly beneficial. We present a system that enables fine-grained personalized control of third-party access to patients’ electronic health records, allowing individuals to specify when and how their records are accessed for research purposes. The use of the smart contract based Ethereum blockchain technology to implement this system allows it to operate in a verifiably secure, trustless, and openly auditable environment, features crucial to health information systems moving forward.

Keywords: Electronic Health Records; Health Information Systems; Technology

Introduction

Medical data, both routinely collected and specifically studied, is increasingly being recorded, represented, and stored electronically [1]. Having access to these resources in electronic form is immensely beneficial to researchers, allowing novel research methods to be applied over large volumes of data in a way that would not have been possible even a decade ago [2, 3]. This switch to the digital does, however, bring with it problems relating to the physical and ethical security of medical data [4]. Data stored electronically is much easier to copy, distribute, and mine for confidential information. Breaches of security and the loss or misappropriation of data negatively impact the public perception of medical research and threaten to bring down regulatory restrictions that will prevent or hinder future research [5]. The current state of information security within the medical informatics domain makes controlling and identifying such breaches difficult [6].

Further, there is a gap between the ideal needs of the research community and ethico-legal restrictions on the use of personal medical record data [7]. The research community’s desire for essentially unfettered access to data is checked by the legal responsibility of data owners to guarantee the privacy of the patients whose data they protect. There is also a recognized need for public involvement in the research process [8] and even where patient data is de-identified and used in the aggregate, granting of explicit consent for data use has been identified as the preferred model for half of all patients, with increased awareness of Electronic Health Records (EHRs) impacting positively on willingness to consent to research [9]. The best way of achieving and maintaining this balance between trust, security and admittance of public participation is an open question [10] — how can medical data be shared in a way which still, at its core, guarantees as far as possible the security and integrity of the data being shared? Addressing these challenges will be of crucial importance to health informatics moving forwards.

We present a proof-of-concept system for enabling fine-grained specification of access control policies as pertaining to third-party access to electronic health records on an individual level, which goes some of the way towards tackling these issues. Giving patients control of access to their own records whilst giving research organizations, possibly from the private commercial sector, the ability to directly reach out to patients and request access to medical data, opens up a series of issues around trust and security. We have implemented this system using the Ethereum platform, a modern, smart contract based, distributed ledger system [11]. This choice of platform not only allows for a natural expression of a solution to the problem we address but also explicitly addresses and solves the underlying complex issues of trust and security.

Methods

Enabling direct patient involvement in controlling the use of medical data, and doing so in open and secure manner will enhance both uptake and acceptance of medical informatics platforms aimed at enabling access to research data. We aimed to develop a core Application Programming Interface (API), for use as a service within a wider platform, that would enable a permission system through which patients could both specify who could access their records and to review the uses to which their data have been put. We identified this as the most fundamental building block of any system that would purport to enhance patient control in a research-oriented informatics system.

The requirements for the design of the API were gathered through an analysis existing systems for sharing and reuse of medical data deployed within the North of England [12]. This gave us an overview of the core functionality required by such a system.

The design of the API proceeded first with the identification of the key class of actors who would interact with the system. A series of core requirements based around ensuring requisite levels of security, trust environment, and transparency were then developed. Following this development, a series of use cases were produced that specified the ways in which the system actors would be able to interact with the API in order to achieve the overarching goal of enabling patient control of access requests to EHR data.

In implementing the system to address these use cases we chose distributed ledger technology ("DLT") as the underlying technical implementation. DLT is the mechanism, in terms of
data structures and associated computational methods, underlying the Bitcoin cryptocurrency, in which the specific instance of DLT is the Blockchain [13]. The driving use case behind the design of the Blockchain was the desire to allow for a decentralised transaction ledger; the provision of a canonical global account balance for all holders of the Bitcoin currency, without reliance on a trusted third party as a point of control [14]. The Blockchain implementation further provides both a public key–based infrastructure for account identification and control, and a ‘mining’ mechanism (a computational competition which both incentivizes hosting of the peer-to-peer Bitcoin network and solves the so-called ‘Byzantine Generals problem’ — that of guaranteeing consensus amongst distributed network nodes containing potential bad actors) [15]. Since its conceptualisation DLT found extended use across a range of application areas [16] and has been extended with the addition of ‘smart contracts’, a means of adding distributed computational processing to the underlying transactional ledger [17].

The core features of DLT were identified to meet the specified system requirements. Specifically, we chose the Ethereum Platform [11] to host the API given an assessment of its capabilities in producing a system to fulfil the outlined use cases. Ethereum itself provided both the core DLT blockchain capabilities allowing for hosting within a trustless, secure environment, and a smart-contract implementation allowing for the programmatic implementation of the API directly on the platform itself.

Results

Presented in the following section are the results of our design and implementation in terms of the actors we identified, the core requirements, the driving use cases and a specification of the API.

The core actors within the system were identified as follows:

- **Public Participant** — someone for whom associated EHRs are accessible within some system who will be granted control of a permission system for accessing those records.
- **Research Organization** — Representing an organizational entity that wishes to request access to EHR data for research purposes.
- **Data Custodian** — An organizational entity with ultimate control of source electronic medical data

We identified the following underlying requirements for the system:

- **Trustless** — Reliance on a third party to maintain control of some or all of the system functionality decreases trust and adds a single point of failure to the system.
- **Incentivized** — With use of a distributed technology, it is required that participants within the system should share the burden of hosting the system itself. A mechanism is needed to ensure this happens.
- **Secure** — The system needs to be secure in that it must prevent actions being performed by entities or actors not specified as being allowed to perform those actions.
- **Identifiable** — Actors need to be strongly and verifiably identifiable within the system. Recognizing that key management by the lay public is a difficult issue, formal identity management may be delegated to other actors (for example Data Custodians performing actions within the system on behalf of users)
- **Transparent** — Perceived trust in the system is crucial so all actions that take place within the system need to be publicly auditable.

The following use cases were identified as the drivers of the API design:

- A **Research Organization** can publish a request for data in the form of a Research Proposal. The Research Proposal will outline what medical data is required for the research, the form of that data and the limits of its use.
- A **Data Custodian** can vet a Research Proposal and decide whether it is published to Public Participants whose data that custodian safeguards.
- A **Public Participant** can set a general preference for how their medical data should be used. This will allow options for allowing or denying all requests, or granting permissions on a proposal-by-proposal basis.
- A **Public Participant** can view lists of Research Proposals which would utilize their private medical data.
- A **Public Participant** can specify an option against a Research Proposal indicating whether or not they will grant permission for the use of their data within that proposal.
- A **Data Custodian** can request a list of patients who have consented for a particular Research Proposal

We chose to implement the code for enacting these use cases using DLT. Through creating a distributed ledger instance, records of what proposals have been offered and which participants have granted, either implicitly through global options, or explicitly against a particular proposal, are recorded within the ‘blocks’ that form the ledger. These use cases were then implemented directly in the form of smart contracts deployed within the blockchain instance. A smart contract is an executable piece of code that references the current state of the ledger and can write back to it. Smart contracts are authored in Solidity, a Turing complete programming language, broadly similar in syntax and structure to javascript. These were compiled into Ethereum compatible byte-code and hosted on the ledger instance. An illustrative extract of such a smart contract is given below.

![Figure 1 – A Portion of a Smart Contract](image)

Accounts for actors within the system (patients, research organizations and data custodians) were either created directly as user accounts within the Ethereum system (with associated public/private key pairs), or, in the case of patient accounts,
managed via a data custodian account -- that is, public participants controlled their accounts via functions exposed by the data custodian entity. This mitigated the difficulty of requiring public participants in the system to manage their own public/private key pairs.

The hosting environment for the API consisted of a private instantiation of the Ethereum platform -- one entirely distinct from the canonical, publicly accessible peer-to-peer instance. Further, node hosts were set up inside in virtual machines and firewall rules were in place to restrict peer-to-peer connectivity to other known hosts. Access to the system in its entirety is then ultimately controlled through network-level security.

Discussion

We chose distributed ledger technology as the underlying technical implementation for this service as it provided, as an integral part of the technology itself, a secure framework that enables deployment within a network not reliant on a central point of trust. As stated, establishing a balance between the desires of the research community, the ethical and legal obligations of data custodians, and the ultimately decisive needs as well as the perceptions of the public is of key importance in establishing sustainable medical informatics frameworks enabling the use of electronic health data. The nature of distributed ledger technology, in that it provides an auditable, accountable framework removed from a single point of trust (and hence possible failure or compromise), makes it a natural fit for such systems. Identity management is a fundamental requirement of any such system — inability to establish and ensure identity across a system immediately invalidates any claim to security. Again DLT is built around the concept of identity and public key management, providing a base on which to build systems where identity is a crucial component. Smart contract functionality is provided by the Ethereum platform.

The blockchain data structure is designed for redundancy across a network of peers and smart contract mechanisms deliberately replicate computation of programmatic structures across all nodes in the network. Whilst this provides benefit, as mentioned, in the areas of trust and security it does introduce computational inefficiencies. These raise potential issues in terms of the use of the technology in a real-world setting, particularly one at scale. However, the use cases that the design of the system was based upon do not require absolute real-time instantiation across the system. The preferences set by users and the requests for research data do not need immediate processing or acting on by external services. As such this mitigates to a degree the natural inefficiencies in the system. The reliance of current distributed ledger technology on essentially arbitrary computation (token mining) again introduces inefficiencies into the system. The original aim of the mining mechanism in the Bitcoin scheme — that of incentivizing distributed participation and as a means of introducing and distributed currency — does not translate entirely into an environment with a higher degree of trust between participants. Such mechanisms can still be leveraged as a means of ensuring fair participation in the ecosystem; for example with tokens, rather than providing economic value, it can be used as a proof-of-participation and required for ongoing use of the system.

Distributed ledger technology, in particular Ethereum, are new and hence relatively untested technologies. Whilst their primary use case as financial tools with intrinsic economic value incentivizes both secure implementation and testing through real world exposure, bugs and security flaws are do persist. Further, the rapid pace of innovation and evolution of the platforms will carry increased risks of potentially harmful design flaws becoming apparent.

Constant evaluation and auditing of the underlying technologies in terms of monitoring and addressing security flaws will therefore be crucial in the future use of this technology. the current system we have developed exists as a stand-alone API with the explicit design goal of acting as a component in a wider service oriented medical informatics platform. Future work will address this as we aim to roll out a test deployment of the system within an infrastructure for enabling actual access to data within a real-world setting. Also given the potential issues surrounding public perception of distributed ledger technology, both in respect to it being a nascent and relatively untested technology, and its association with negative reporting and use within black markets, work will be done on gauging public attitude towards the use of the technology within a healthcare environment.

For any medical informatics system the key driver of its implementation, and the ultimate gauge of its success, will be measured in the benefit it brings to medical care and practice. In moving forwards the state of the art in terms of security, privacy and accountability, distributed ledger technology has the potential to add a significant degree of trust to the functionality of medical informatics systems. With this enhanced trust will come the ability to utilize medical data within richer settings and with a wider range of participants — something that will ultimately improve medical care and practice moving forwards.

Conclusion

We have identified a series of key requirements for enabling enhanced patient control of EHRs and have developed a proof-of-concept API meeting these requirements. Distributed ledger technology was chosen specifically to meet what we see as the fundamental issues in health informatics, namely trust and security. Whilst problems do exist, particularly with respect to the fundamental inefficiency and current immaturity of the technology, distributed ledger technologies offer unique solutions in the health informatics domain and will inevitably see increasing use in the field in future.

Enhancing Children's Safety by Barcoding Implementation at Breast Milk Feeding

Mariana Daus, Thelma Maydana, Daniel Rizzato Lede, Daniel Luna

Department of Health Informatics, Hospital Italiano de Buenos Aires, Argentina

Abstract

When newborns remain hospitalized in a neonatal intensive care unit, they are often unable to feed themselves and receive human milk through enteral nutrition devices such as orogastric or nasogastric probes. Therefore, the nursing staff is responsible for the fractionation, storage and administration of human milk. Breast milk has a great biological complexity being the optimal food for the baby to provide all the nutrients needed. At the same time, it is a bodily fluid that carries the risk of disease transmission if not administered properly. Patient safety should be a priority in healthcare, and health information technologies could be used to avoid preventable adverse events. Barcoding technology has the ability to accurately verify patient identity and prescription accuracy before milk administration. This paper describes the steps followed to implement breast milk barcoding technology in an academic tertiary hospital.

Keywords:
Breast Feeding; Barcoding; Patient Safety

Introduction

The Hospital Italiano de Buenos Aires has been engaged in quality and safety improvements for a long time. Currently, we are working to implement the barcoding verification technology in the circuit of human milk.

Human milk is the first natural food of newborns, and it provides all the energy and nutrients they need during their first months of life. Further on, it continues to provide at least half of their nutritional needs during the second half of the first year and up to a third during the second year of life. It promotes sensory and cognitive development, and protects the baby from infectious and chronic diseases. It has proven to reduce child mortality by preventing childhood diseases, such as diarrhea or pneumonia, and even favors early recovery in case of illness [1].

When a baby is premature, ill, or away from her mother for any reason, it is very important to promote breastmilk manual or mechanical extraction for baby feeding. In a hospital setting, health professionals are responsible for the babies’ feeding if they cannot breastfeed naturally. Preterm newborns before week 32 do not have an effective suck, so enteral feeding is done by orogastric probe with gavage technique.

Obtaining the human milk requires breastpumps and sterile circuits with aseptic technique performed by trained mothers, ideally monitored by specialized staff [2].

In the Neonatal Intensive Care Unit (NICU), the nursing staff is responsible for the fractionation, conservation and administration of the human milk. At every step, it is essential to verify the patient identity for safety and quality of care. The “5 rights” rule recalls each element that should be verified before administration: the right patient, the right medicine, the right dose, the right path, at the right time. Several strategies are constantly designed to reduce the incidence of errors in healthcare. A great deal of support has been found in information technology, which has already shown enormous benefits for medicine. Barcode is a simple but very useful technology inherited from commercial industry. Its implementation and universalization in healthcare has been endorsed to check the patient information for their safety. This simple system allows quick, safe and error-free access to meaningful information required in diagnostic tests or during treatment administrations [3].

The objective of the present paper is to describe the former process of the breast milk circuit in our hospital, and the subsequent steps taken to design and implement the barcode verification technology.

Methods

Setting

The Hospital Italiano de Buenos Aires (HIBA) is a non-profit health care academic center founded in 1853, with over 2,700 physicians, 2,700 other health team members (including 1,200 nurses) and 1,800 administrative and support employees. The HIBA has a network of two hospitals with 750 beds (200 for intensive care), 41 operating rooms, 800 homecare beds, 25 outpatient clinics, and 150 associated private practices located in Buenos Aires city and its suburban area. It has a Health Maintenance Organization (Plan de Salud) that covers more than 150,000 people and also provides health services to another 1,500,000 people who are covered by affiliated insurers. Between 2013 and 2014, over 45,000 inpatients were admitted to its hospitals. There were 45,000 surgical procedures (50% ambulatory) and 3,000,000 outpatient visits. In addition, the HIBA is a teaching hospital, with over 30 medical residency-training programs and 34 fellowship programs. There are currently 400 residents and fellows in training.

Since 1998, the HIBA runs an in-house developed health information system, which includes clinical and administrative data [4]. Its Electronic Health Record (EHR) system called Italica, is an integrated, modular, problem oriented, and patient centered system that works in different clinical settings (outpatient, inpatient, emergency and home care). Italica allows computer physician order entry for medications, medical tests, and storage and retrieval of tests results. It also includes images through a picture archiving and communication system. It has been recently certified by the HIMSS as level 6+ in the Electronic Medical Record Adoption Model (EMRAM), being the first hospital in Argentina and the second in Latin America reaching this stage [5].
The HIBA achieved Joint Commission International safety and quality certification in 2015 [6]. One major addressed issue was the right identification of patients. To this end, in 2010 the Department of Health Informatics developed and implemented an inpatient bracelet identification system with barcoding technology. This code can be scanned to verify patient identity before every intervention (patient transfer, medication administration or other procedures).

Nowadays, the process of scanning the tag of every medication before its administration is performed just in the Adult Intensive Care Unit. In order to certificate EMRAM level 7, we should perform barcoding verification in every inpatient setting, for each substance administration (including breast milk, human blood products and medications).

The neonatal intensive care unit (NICU) is divided into three different areas: the Intensive Care Unit (22 beds), the Hospitalization, and the Follow-up Clinic for premature and high-risk newborns (25 beds).

Direct mother breastfeeding does not need patient-substance verification, but sometimes the hospitalized newborns are not able to feed by suction and need other route for enteral nutrition, thus requiring special assistance from nurses [7]. Thus, we focused only in the intensive care sector where the circuit of breast milk extraction, storage and administration takes place.

**Methodology**

We carried out an observational analysis of the processes, supported by bibliographical evidence. We assessed the areas of lactorium (lactation room), the milk fractionation room and the neonatal intensive care room (NICU) by reviewing the whole circuit: first the extraction of breast milk, storage, sterile fractionation and finally the milk administration in the patient unit. This revision work was guided with project management methodology [8]. Each process was plotted with flowcharts.

**Results**

**Process traceability**

We plotted the milk process in a flowchart using all the information collected during the study. Afterwards, we drew a journey map highlighting risk and opportunities of each step (Figure 1).

**Breastmilk feeding prescription**

The circuit starts with the feeding prescription. Pediatricians fill the milk order through a CPOE, but in plain text (not structured) including heterogeneous data. As these prescriptions are not linked to the medication label printer, nurses must read the instructions and label the milk manually.

**Lactation room**

The first observed place was the lactorium. It is a room specially equipped for the extraction and storage of human milk, where a breastfeeding woman can use a breast pump in private. It has 3 electric pumps and a refrigerator. Each mother uses a breast pump kit (with sterilized materials) and then discards it for sterilization. This work is supervised by specialized staffs, which coordinate the activities of the sector and educate each mother to correctly perform the extraction technique. They are responsible for printing patient identification labels from the EHR containing the baby’s hospitalization data. These labels are stored in separate plastic folios in a common folder located inside the lactorium.

Staffs verify the newborn feeding prescription, and deliver each patient’s label to the corresponding mother to identify their milk every time it is extracted.

The women put their milk in sterile flasks labeled with the babies’ identity and then handwrite date and time, before storing them in the refrigerator.

**Milk fractionation room**

This area is intended for sterile manipulation and fractionation of the milk. It is of vital importance, since it prevents potential risk of cross-infections [9]. Three nurses are trained and assigned to this process.

![Figure 1 - Process journey map](image-url)
Initially, the newborn feeding prescription is checked for each patient in the EHR through a PC located in the room. At the moment, it is not possible to print this type of prescriptions in specific labels. Therefore, nurses use generic labels with patient ID to identify the milk syringes.

One nurse brings the bottles from the lactorium's refrigerator. The milk from each bottle is divided into syringes following the prescribed dose. Afterwards, the syringes are labeled and stored in the corresponding patient's drawer, located in a special refrigerator of this sector.

If any of the milk bottles is not going to be used shortly after, the nurses store it in a freezer to extend the expiration date.

Neonatal intensive care unit (NICU)

There are nine nurses in the neonatal intensive care unit; i.e. two nurses per patient.

The nurses must pick the milk syringe from the refrigerator and go to the patient bedside. Every time an intervention takes place, it is necessary to validate the patient identity by visual confirmation of the incubator label and the patient bracelet. After checking the five rights, they administer the milk to the patient through the corresponding device. Finally, the administration should be recorded in the EHR.

Proposal for improvements in breastmilk prescription

CPOE for pediatricians requires a software adaption to include a specific module for breastmilk feeding prescriptions.

We searched the data warehouse for general orders containing milk prescriptions of the last 6 months to look for examples and patterns. We defined the minimum fields required to structure the posology: type of milk (human), dose, route, infusion method, infusion speed, and frequency.

We sketched initial pen and paper prototypes and validated them with final users. Afterwards we made high fidelity prototypes emulating the interface for medication prescription (Figure 2).

Proposal for improvement in the Lactorium

There are risks of human error in the current process:

1. Asynchronous label printing (long time ahead of extraction) hinder direct patient identity validation.
2. Storage of pre printed labels in plastic folios can lead to wrong bottle attachment.
3. The handwritten extraction date and time can be erroneous or missed.

Therefore, to fulfill the first picking verification it is suggested to corroborate the mother and child’s identity. It requires the following modifications:

- **Hardware**: to place a PC with a label printer and a barcode scanner in the Lactorium.
- **Software**: to develop a tool to verify the mother ID by barcode scanning. When the system validates her relationship with the baby, it then prints a label for each bottle of milk. The mother must carry an identification wristband that should be printed in advance at Admission office.

The mother should read the wristband barcode with a scanner through a simple interface of the software (as shown in Figure 3). If the system validates the identity, it would print a label synchronously just prior to milk extraction, adding a timestamp. We suggested including a calculated expiration date, according to storage temperature. [10]

Proposed improvement in the Milk Fractionation Room

The nursing staff is responsible for the storage and fractionation of the milk. There are also risks of human error in the current process:

1. **Fractionation**: staff may confuse the EHR feeding prescriptions or even crossing over with another patient, as they check them just by observation.
2. **Disposal of surplus milk**: the bottle can miss the timestamp, thus preventing the staff to store it in the freezer, as they can not calculate expiration date.
3. **Labeling of prepared syringes**: staffs may place the wrong label or even miss it.

![Figure 2 - Human milk prescription prototype.](image-url)
Therefore, a second picking validation is necessary to corroborate that the right prescription is prepared with the right sample of milk. It would require the following modifications:

- **Hardware**: adapting the existing PC, adding a barcode scanner and a label printer.

- **Software**:
  - Adapting the nurse preparation workflow from the EHR (just intended for medications) to incorporate breast milk prescription.
  - When selecting the prescription to prepare, if the scanned bottle barcode is from the right patient, the system will print a new label containing a detailed description (patient name and ID, type and amount of milk, route and frequency) and a new datamatrix code.

**Proposed improvement in the NICU**

Prior to milk administration, a third verification is needed to check the right patient identity and the other four rights of the prescription (milk sample, dose, route, time) by barcoding. This would require the following modifications:

- **Hardware**: incorporation of a barcode scanner in each patient unit (attached to the bedside device: tablet or computer).

- **Software**: adaption of the nurse module of the EHR to allow barcode synchronous verification before milk administration in the patient unit.

**Discussion**

We intended to design and implement a reliable system for closed loop breast milk circuit. Barcoding technology can enhance patient safety by verifying the identification at the time of the removal, storage, fractionation and administration of human milk, and establishing a physical barrier that can decrease the errors due to human factors in every stage of the circuit [11].

We started our project defining objectives, tasks, desired scope, and work equipment. During the research it was possible to define the actors, the events, the risk, and opportunities for improvement. We could analyze the best way to achieve a rate of verification by barcoding greater than 95%.

The incorrect administration of breast milk involves several complications: may cause the transmission of diseases, causing additional examinations to the patient and the loss of confidence of their relatives in the health professionals or the institution.

The manual verification processes of the five rights for medication administration are prone to human error. The barcoding of breast milk provides a simple technological solution to improve safety in the preparation and management of the product because it acts as a barrier that can prevent adverse events. The barcode is read by an optical scanner, which is routed directly to an active computer application at the time of reading.

The most important negative risk would be the resistance to change of the staff involved in the implementation of new tasks. It is of the utmost importance to create solution strategies before the events happen and promote the participatory change, making available the new knowledge to the individuals or groups involved [12].

The successful implementation of the barcode in the human milk will be affected by the improvement of the process before they start the automation, overcoming the barriers such as the time and expense of training, the costs of software and hardware, the flow of work and avoid temporary solutions that can weaken the security of the processes [13].

The goal is to apply the existing knowledge and validate it in the design of procedures that help to satisfy a need. The power plan in advance the steps needed to guide the work of the team toward the achievement of the goals, would establish corrections, determine results, and implement new strategies where necessary [14].

**Conclusion**

In this work we describe the current events and the necessary modifications to achieve the implementation of barcoding in the circuit of extraction, fractionation and administration of human milk, adapted to our local process. This allows the traceability of the milk from the time of removal until the administration. A culture of safety involves users, structural elements, processes, instruments and methodologies based on evidence that minimize the risk of adverse events.

A Mobile System for Music Anamnesis and Receptive Music Therapy in the Personal Home

Kerstin Denecke

Bern University of Applied Science, Bern, Switzerland

Abstract

Receptive music therapy is active hearing of music that is specifically selected to cause a certain effect on a person, such as pain reduction, mental opening, confrontation etc. This active, guided hearing could be helpful as a supporting ritual for patients at home and could extend traditional therapy. However, patients are often unable to select the music pieces that might be helpful for them in a current situation. We are suggesting a self-learning decision support system that allows a patient to answer questions on music anamnesis, ready for inclusion into an electronic health record, and which enables a therapist to compile a therapeutic music program for the patient at home. Beyond this, the system also suggests appropriate music and duration of listening based on the patient’s reported current mental state. In this paper, a concept for such a mobile system for receptive music therapy will be proposed.

Keywords:
Music Therapy; Decision Support Techniques; Mobile Applications

Introduction

Music therapy is defined as “the use of sounds and music within an evolving relationship between patient and therapist to support and encourage physical, mental, social, emotional and spiritual well-being.” [1]. It is a young treatment method indicated in patients with autism [2], dementia [3], depression [4], pain [5], and other conditions. In 2005, it was included in the DRG catalogue for multimodal clinical pain therapy. The objective is primarily to help clients improve their health in several areas, such as cognitive functioning, motor skills, emotional development, social skills, and quality of life. To achieve this, patients are encouraged to experience music by free improvisation, singing, listening, and moving to music. Active and receptive music therapy can be distinguished. We are focussing on receptive music therapy in this paper.

Receptive music therapy comprises "active hearing of selected music pieces under certain conditions" [6]. The difference from everyday listening of music is that certain effects are to be achieved, e.g. a confrontation, spiritual opening etc., which requires a careful selection of the music pieces. In addition, there is a concrete guide which encourages listening.

Even though the therapist-patient relationship is important in this context, there are use cases where it would be helpful for patients and for the treatment – similar to doing physical exercises at home – if aspects of receptive music therapy could be continued in a guided manner in the personal home of a patient. For example, from the treatment of patients with chronic pain, it is known that patients can be equipped with a therapeutic program for home use, but this requires exact specification of usage to create an individual ritual against pain [7]. The problem is that clients have difficulties in deciding which music would be good for them in a particular situation. They could even select music that could harm them or achieve undesirable results. Existing music compact discs (CDs) for individual music therapy, e.g. by W. Zeitler [6] are described very well with a lot of practical experiences. Nevertheless, Zeitler reports that the help-seeking clients often do not understand these descriptions and would choose some music which does not help them.

A decision support system implemented on a mobile device such as a smartphone or tablet as designed in this paper could help in selecting the appropriate music and make suggestions according to a therapy plan. More specifically, the objective of this paper is to design a system that supports a patient in using the therapeutic capacities of music therapy at home. Taking existing practice into account, the system will in particular support the therapist in collecting music anamnesis and in creating therapeutic music therapy programs. Starting from a requirement analysis, we are developing a concept for a mobile system supporting music therapy.

Using digital media in music therapy has gained interest in the last couple of years. Computers, smartphones, and tablets are mainly used for recording, composing, adapting music pieces and accessing music libraries [8-9]. Several case studies have illustrated multiple uses of technology with young adults [10-11]. In particular, recording technologies are exploited for enabling immediate capturing of spontaneous music making during therapy session or with others. There are apps available that allow users to arrange music into loops (e.g. Relax melodies, http://www.ipnossoft.com/app/relax-melodies/) in order to create a personal meditation or relaxation program. However, to the best of our knowledge there is no system available that supports the music anamnesis and therapeutic home usage we are considering.

Material and Methods

We performed a requirement analysis by means of a structured questionnaire. The current and target situations had to be described together with functional and non-functional requirements. The questionnaire was completed by one music therapist. Additionally, we collected requirements from existing literature on music therapy. Afterwards, we designed the architecture for the system and developed first mock-ups. In this section, we are describing the current procedure in music therapy and possible usage scenarios for the system as
referred through the requirement analysis. Further, we are summarizing the requirements.

**Music Anamnesis and Music Therapy**

Traditionally, within receptive music therapy, the therapist selects music and plays the recorded music to the patient. Afterwards, a discussion on the feelings caused or other effects takes place. A main characteristic is that selection of the music focuses on symptoms of the patient and his/her personality. Three main issues determine selection of music within the therapy session: the music anamneses which are habits and preferences of music listening of the patient, the current situation (emotional or health state) and the therapeutic goal. We describe these three aspects in more detail below.

In the first session, the music therapist makes a music anamnesis. For this purpose, questions are directed to collect information on the patient’s experiences with music in childhood and current life, preferences in music listening, etc. (see Table 1). Additionally, emotions caused by music listening will be identified and the patient will be asked to judge personal experiences with music. Further, it is important to determine habits in music listening and preferences towards certain instruments, genres or music pieces. The objective is not to identify the preferred music – this can cause the person to experience past emotions that can become problematic in the current situation. The objective of the music anamnesis is to get an idea of the categories of music that could help a person in situations targeted by the therapy.

For the current situation of a patient, his or her mental state is assessed by asking for current feelings and symptoms. Consider for example a patient suffering from chronic pain. The current situation comprises that pain at the given time and the general mental constitution (e.g. feeling entirely surrendered to the pain, depressed, afraid). The therapeutic goal has two dimensions: the long-term goal of the entire therapy and the goal for a specific session. It is specified in the discussion between patient and therapist.

The information on all three aspects forms the basis for selecting appropriate music pieces and creating a specific therapy program for a patient.

**Use Cases**

1. **Music Anamnesis and Preparation of a Therapy Program**

Consider a patient with chronic pain. For him it is important to regularly use a music therapy program for pain relief. The patient answers questions in the music anamnesis through the music therapy application as preparation for the therapeutic session. The session is held as usual, but the therapist can begin with some knowledge of the patient’s background since the anamnesis has been completed by the patient in advance. During the session, the therapist gets an impression of the mental state of the patient and they jointly define the therapeutic goal. The information in the anamnesis can be extended by the therapist in the session. This information is entered by the therapist into the system as part of general documentation which is stored in the electronic health record of the patient. After specifying the therapeutic goal, the system suggests music pieces supporting the therapeutic goal and considering the preferences of the patient as derived by the music anamnesis. The therapist can select music pieces that are compiled by the system later on to training programs for the patient at home. The system helps to select appropriate pieces and to create therapy programs.

2. **Running the Therapy Program at Home**

The same patient suffering from chronic pain starts the mobile application at home. The app asks the patient for his current mood and health status. Depending on the responses, the application compiles an appropriate program of suitable length based on pieces preselected by the therapist. The program is suggested to the patient. After listening to the music and some relaxation time, the system asks for feedback in terms of the mood of the patient or changes in symptoms after listening to the program. This information is forwarded to an electronic health record as a structured report that contains the date, length of listening, initial health state, and state after listening. In this way, an anti-pain ritual is created in the patient. The feedback information helps the system adapt its program creation strategy. The therapist also receives feedback on whether a music piece was helpful or not, which can be considered in the follow-up.

**Requirements**

From these use cases, we can derive the system objectives: to increase quality of life and provide music therapy for patients that can be continued at home. In terms of quality, the system will support patients in listening to an appropriate music program that is directed to the therapeutic goal. The economic value is that therapeutic sessions are accompanied by a continuous practice which can support the effects of therapy. The music anamnesis can be collected already in a digitized manner, available for the first therapy session.

We collected several functional and non-functional requirements. Functional requirements include:

- Supporting a music anamnesis
- Capturing current emotional or mental state or constitution of a person before and after listening
- Proposing a helpful music therapy program, taking into account recorded music history and current constitution of the person as well as the therapeutic goal and recommendation of the therapist
- Allowing listening to receptive music therapy program
- Collecting feedback and reconsidering emotional and mental state according to the therapy program (independent learning of the preferences of a person)
Non-functional requirements include: 1) standardized information modelling of the music anamnesis, 2) standardized reporting of home therapy sessions, 3) connection to an electronic health record to store the anamnesis and reports of therapeutic sessions at home, 4) consistent graphical user interface (GUI), also suited for patients less experienced with digital devices, and 5) response time less than 1 second.

Additionally, there are quality standards relevant for music applied in medical contexts [10] which need to be considered in the implementation of the system. This means, not each music piece is appropriate for usage in music therapy. Some relevant aspects are: a music piece needs to be defined (composing criteria, interpretation, instruments), selected according to the indication, should have a known profile of effect and the dosage needs to be specified (volume and duration of listening) [10].

Results

The system is designed as a service-oriented system architecture. Figure 1 shows the four major components of the architecture. It comprises a client-facing application acting as a user interface and a server application orchestrating single services. Processing services include the computational components, and resources encapsulate data that need to persist for the system to work properly. Details such as acquiring data from a client application or from multiple data sources of several types are not shown explicitly in the figure and will not be explained in detail. The components of the architecture are described below in more depth. First, a general overview is provided followed by a detailed description of single components.

Figure 1 – System architecture comprising client, server, processing services, and resources

Architecture

The Client is a system user interface, partially designed as a conversational user interface to maintain a conversation-like style particularly in the anamnesis part. It allows starting the system, i.e. for patients this includes the anamnesis, and the therapy program. For physicians, the user interface presents the anamnesis, enables inputting the therapeutic goal or adapting the anamnesis, and supports compiling appropriate therapy programs.

The Server is responsible for interaction between client and processing services, invocation of services, and communication with external applications. In its role as service orchestrator, it invokes services in the right order and transmits the results of one service as input to the next service if required. It prepares responses of the processing services, collects results of the services and transmits the results to the client.

The Processing Services realise the actual processing. They might be independent from each other or the output from one processing service is required as input for another. We identified four different groups of processing services that are required to realise the music therapy app. These include: Data Collection and Storage Services, Filtering Services, Semantic Services, and Visualisation Services. Details are given in the following paragraphs.

Data Collection and Storage Services are responsible for collecting and storing data from and to different resources. One service retrieves the questions for doing the music anamnesis from a knowledge resource (see below) and forwards them to the GUI. Another service is needed for storing the completed music anamnesis into an electronic health record or for retrieving a stored anamnesis for a given patient. The data entries need to be stored in a structured manner for interpretation by the system later on in the music recommendation phase. Furthermore, it stores a report on the therapy program the patient received through the app including his feedback on health status in the electronic health record (EHR). It also stores information on the patient’s mental state, frequency of listening, and music anamnesis – i.e. all information that is of relevance to the music therapist and which helps in monitoring progress. An additional service provided is retrieving music from music libraries or even data from a user’s desktop as required.

Filtering Services mainly aim at supporting the therapist in selecting appropriate music pieces from the database. Filtering criteria may include user-specified preferences as described in the music anamnesis, the specified therapeutic goal, etc. One potential filtering service is a recommendation service that makes suggestions for appropriate music pieces for a given patient or composes a therapeutic program suited for a specific patient given his/her mental and physical state. The therapeutic program that is created could for example be structured considering the phases in a therapy session where according to Zeitler [6] music of different characteristics is appropriate:

1. Salutation (music is rather slightly touching),
2. Warming-up (releasing music, more touching),
3. Confrontation (confronting music),
4. Closing and calm down.

For home usage, confronting music should not be included to avoid negative impacts.

Semantic Services provide music and text analysis functionalities on different levels of granularity. Their main task is to analyse music pieces, to select appropriate pieces when semantic information is unavailable. Additionally, semantic services are required for structuring and interpreting conversation with the patient through the conversational user interface. However, there are also services that are necessary to interpret the responses given by the patient in the conversational user interface.

The Visualisation Services realise the visualisation and result presentation of the application. Visual alerts, a conversational user interface, and scales for answering questions are some options that might be relevant. Additionally, the information from the music anamnesis is visualised to improve readability and perception of the information by the therapist.

Some of the processing services presented before require additional knowledge which is represented in the proposed architecture as the Resources component. Two different kinds of resources can be distinguished. Knowledge resources contain background knowledge on a patient including the music anamnesis, therapeutic goal, and preferences in listening. This can be considered a patient information model.

One knowledge resource is the questionnaire for music anamnesis. In order to recommend appropriate music to a given music anamnesis and therapeutic goal, corresponding knowledge needs to be available, i.e. knowledge on effects of music on patients in specific situations.

Music needs to be available to the system. It can be either integrated as resources or retrieved from external applications. For each music piece, knowledge on the effects it might cause and the type of music need to be available. Another option would be to develop algorithms that do such classification automatically.

Figure 3 shows the information flow for the use cases separated into three parts: music anamnesis, creating music therapy program, and music therapy. The structured report that is stored at the end contains information on the music pieces the patient was listening to, initial emotional and health state and feedback afterwards.
The music anamnesis will be realised using a conversational user interface, i.e. it resembles a short message function. This has the benefit of creating the impression of being interviewed by the therapist. Example queries in the music anamnesis screen is shown in Figure 2. Additionally, Figure 4 shows the user interface for starting the assessment of the current health state and mood.

Discussion

In this paper, we introduced possibilities of information technology to support receptive music therapy. We introduced a concept and architecture for an IT-based music anamnesis and music therapy support. The next step is to evaluate the anamnesis tool with music therapists. It is clear that the app will not replace the therapist, but it could offer an opportunity for running therapy programs at home, like repeating exercises that have been introduced in a physiotherapy session. There are some open questions for future work. For the actual app, it needs to be clarified where the music is taken from. When using the music library of a patient, it would require an automatic classification of the music pieces in order to support the therapist and system in creating an appropriate program. Taking music from the internet also requires careful selection due to varying quality, interpretation, instrumentation etc. In order to automatically classify music, an open research question is how to formally describe the profile of music in terms of which effects or emotions are caused and whether it is possible to determine such categorization automatically. From a music analysis perspective, it is of interest to describe the relation between composition style and effect.

Secure data transmission needs to be ensured when transferring data to an electronic health record. Further, it needs to be checked whether this system should become a medical device.

The suggested approach tries to respect the current therapeutic procedure. The effect of music on the emotional and health state of a patient is difficult to predict and assess. The objective is to develop means to exploit the power of digital media to guide individuals to helpful, supporting music.

Conclusion

In this paper, we presented a concept and architecture of a mobile system that supports receptive music therapy. One aspect is the music anamnesis which can be filled in by a patient in a digital manner and can be extended during a therapy session. In the future, we will test the music anamnesis app and collect feedback from therapists for improvements. Beyond, the app is intended to enable home use of a music therapy program. It is still unknown to what extent home practicing supports receptive music therapy or improves quality of life for patients, such as those with chronic pain. The app will also allow the running of studies to assess this or similar questions.

Use of Flowchart for Automation of Clinical Protocols in mHealth

Karine Nóra Diasa, Daniel Welferb, Marcos Cordeiro d’Ornellasc, Carlos Jesus Pereira Haygert, Gustavo Nogara Dottoa

Abstract
For healthcare professionals to use mobile applications we need someone who knows software development, provide them. In healthcare institutions, health professionals use clinical protocols to govern care, and sometimes these documents are computerized through mobile applications to assist them. This work aims to present a proposal of an application of flow as a way of describing clinical protocols for automatic generation of mobile applications to assist health professionals. The purpose of this research is to enable health professionals to develop applications from the description of their own clinical protocols. As a result, we developed a web system that automates clinical protocols for an Android platform, and we validated with two clinical protocols used in a Brazilian hospital. Preliminary results of the developed architecture demonstrate the feasibility of this study.

Keywords: Clinical Protocols; Mobile Applications; Flowchart

Introduction
Software development brings together a number of basic macro-activities, which need specific techniques to execute them. Information technology (IT) professionals are responsible for performing these tasks in the software development process. The coding phase of a software is one of the main steps that requires a professional with technical knowledge of programming languages to consolidate the software as a product.

With the adoption of smartphones and tablets, the mobile applications have become popular to solve and to aid in problems of the personal daily and of diverse areas of the society. Consequently, one of the main sectors affected by the growing use of these information and communication technologies is health [1]. Therefore, physicians and other health professionals become users of mHealth and are not limited to the IT resources of health centers, which are precarious in many underdeveloped and emerging countries, as in several regions of Brazil.

While there are many mHealth applications available in the appStore, free of charge or paid, healthcare professionals rely on commercial or academic initiatives to develop health-specific applications once the construction requires specific skills for practitioners in the field. In addition, each existing application addresses a purpose that often does not serve a broad audience, as it is specific and / or limited to certain health care cases and institutions. In this way, the use of these tools becomes unfeasible for a portion of health professionals, mainly to treat local problems from less open regions.

In the scientific literature are found several works that have been intended to develop mobile applications of Clinical Decision Support System [2], [3] and [5]. From these works, despite the divergent proposals, we can observe a pattern in the logic of development, which is in agreement with some representations of the clinical protocols.

The clinical protocol is a management tool that, in the form of systematized documentation or algorithms, normalizes the standard of health care at one point of attention [4]. The systematic reviews and assessments of the benefits and harms of alternative care options are the base to all content that constitutes the clinical protocols and therapeutic guidelines [5]. These practices aim at improving the quality of care, limiting unjustified variations in practice and reducing health costs, and transmitting health teams in the form of a document. Given the importance of clinical protocols in the daily life of health professionals due to the contribution to care management based on structured and systematized knowledge, we propose to use them in the analysis phase to build applications. However, it is important to point out that each health institution elaborates its protocols according to factors and incidences of its locality, for example, the treatment of hospital-acquired pneumonia in a particular region of Brazil, will be different from the treatment proposed for this disease in China.

This work presents a proposal for automatic and generic generation of mobile applications, from the data entry structured in flowcharts. Remembering that the flowchart is an instrument used in the preparation of clinical protocols.

Background
The use of flowcharts for automation of clinical protocols is exploited as a form of computer-interpretable to provide decision-making systems. Classified as task-network model, these types of system formally represent clinical protocols, allowing an execution mechanism to process the knowledge represented in order to provide specific recommendations at point of care [6]. The main feature is the easy representation and human interpretation in graphic form. Many of these systems consolidated in the literature have the interpretation of the knowledge realized through own language for this purpose [7] and [8]. For the formulation of these languages are used primitive structures, logical and mathematical operators, flow control through if-then rules and ontologies. The use of each of these tools is dependent on their own syntax and semantics, in
which they work with groups of characteristics of the clinical protocols and temporal patterns, to control the patients’ clinical situation. Some systems also include the organizational structure of the health system.

In this work, we use the perspective of these systems to carry out a knowledge-driven approach to specific clinical protocols applied to mobile technology. We emphasize that the structure of this work does not allow the temporal treatment of data, because the decision diagnoses are based on the information entered by the user, not being queried in databases, limited the configurations that will be presented in Methods.

**Methods**

The main feature of the proposal of this work is the form of user interaction with the system through flowcharts. In this way, the methodology used in this interaction, based on the definitions of the flowchart elements given by [6]:

- **Oval element** - Each algorithm begins with an oval design, representing a population of patients with a defined characteristic, symptoms and complaints. We can call these oval designs as clinical condition.
- **Diamond** - The diamonds represent the most important clinical decisions. They are decisive for the next steps and we call them decision points.
- **Rectangle** - Represents the specific groups of the care process and the description of diagnostic or therapeutic interventions. We call them Service Process.
- **Circle** – Is the figure of closure, used as "output" every time a process reaches a conclusive stage. From this graphical element, we do not leave arrows.

We describe the proposed logic for these elements in automatic application generation as follows.

**Clinical Condition**

The clinical condition, represented by an oval symbol, is one of the simplest symbols. To describe it, only one clinical characteristic is necessary. Therefore, for the data entry in the system a text field is used. The clinical condition is obligatorily the first element of the flowchart, because from this the flow begins.

**Clinical Decisions**

Unlike the clinical condition, the clinical decisions, represented by the diamond, have several classifications in order to apply the most adequate logic to find the answer. Then, to configure the logic of the clinical decision element, the user must establish the most appropriate type of decision, at that point in the flowchart, in which it can be:

1. Numerical comparison.
2. Decision by calculation.
4. Question.
5. Scoring system.
6. Comparison from reference image.

Each option has a set of steps, which requires the necessary information for each decision logic. Below we describe the configurations of each type of decision.

**Numerical comparison**

To make a decision by means of a numerical comparison, we define as:

- **Fixed values** - where the comparison parameters will always be the same.
- **Variable Values** - where the comparison parameters vary according to the inputs.

It is important to emphasize the terms used in the proposed system and in the present work to determine the characteristics of input values, variables used in the formulation of the decision logic and description of the logic. We determine also:

- **Comparison properties** - The original terms in the clinical protocols. For the system, the comparison properties are essential information to compose the mobile application, because, through these terms, we identify the input fields of values. Example: Days of hospitalization, Temperature; Heart rate etc;
- **definition of variables** - such as fictitious terms to represent the comparison of properties in the formula of decision logic;
- **Formula** - the comparison structure used to carry out the decision logic. We standardize the formulas for each type of clinical decision chosen. Most often, they use the variables associated with logical operators. The user is responsible for describing the formulas according to the type of clinical decision setting chosen.

To compose the formula of clinical decisions based on numerical comparison of fixed or variable values, the logical operators are used.

1. In the description of the numerical formula of fixed values, the character x identifies it as a variable. Thus, for each type of numerical comparison with fixed values, a pattern is identified in the use of the x. For example, for comparisons with a fixed value the x will be at one end associated with a comparison operator and the fixed value, as in (1). For comparison between fixed numbers, x is in the center of the comparison, and the numbers in the borders, as exemplified in (2).

   \[ x = 10 (1) \]
   \[ 0 \leq x \leq 20 (2) \]

2. In another free text field, the user will describe in technical terms what represents the x, so that in the mobile application is described as input value, that is, the comparison properties.

3. The decision by numerical comparison with variable values is a situation where the outcome of the clinical decision is dependent on two or more variable values. Therefore, given the definition of two or more variables, we compare them as in the example (3):

   \[ y \leq x = z (3) \]

4. where y, x, z are variables which represent comparison properties.

5. Because of these clinical decisions, the logic will be binary, i.e. two possible flows.

**Existence of factors**

Another way to make a clinical decision is to check for factors. In this way, the clinical protocols associate absence of factors and/or presence to decide the flow of the process. Including this characteristic in the system, this clinical decision we define through the textual description, in a single field, of these factors associated with logical operators, like “!” (NOT), “&&” (AND) and “|” (OR). We extract the factors from the logic of the exclusion of the operators and we use these words in the mobile
application. As a result of this type of clinical decision, logic will also allow only two flow possibilities.

**Question**
The clinical decision by question does not have any kind of computational logic. This decision depends on the interpretation of facts of the health professional, in which based on a questioning, will indicate if the flow will be positive or negative.

**Decision by calculation**
Like the numerical comparison of variable values, the decision by calculation will require the configuration of properties, definition of variables and description of the formula. However, we describe the formula as an equation through simple mathematical operators. We can use the result of the calculation described for conference (no flow option or only one) or establish classifications. To stipulate the classifications dynamically by the user through ranges of values, we use the logic of numerical comparisons with fixed value. The number of possibilities of flows will be (4). To define the flow for indeterminate ranges we add 1.

\[ \text{flows} = \text{ratings} + 1 \]

\( \text{(4)} \)

**Scoring system**
The scoring system is an operation that takes into account a list of criteria, in which each criterion has a value. In order to establish the value of the criterion, we configure this value in fixed or the user must inform. For example, the criterion value is the same as the patient's age. In case the value is fixed, the treatment of the criterion is as the logic of the existence of factors.

By means of the sum of the values, of the selected criteria, we obtain the diagnostic result. To establish the result, in turn, we use the predetermined classifications. The number of possibilities of flows will be as in (4).

**Comparison from reference image.**
The comparison from the reference image does not require computational effort and is an intrinsic feature to other forms of clinical decision. Through the insertion of images, these can help the viewer user to make decisions.

**Customer Service Process**
The service process, represented by the rectangle, has the simple objective of providing information. It is usually associated with a clinical decision element. Therefore, it is the ideal element to describe textually the procedures given by the flow.

**Simulator**
The simulator has a structure, in the development interface, of logic and screens identical to those of the Android application. As the user mounts the flowchart, it is possible to check the expected outputs, according to the element types and their relationships. Therefore, the simulator is a way for the user to carry out case tests before the application is generated.

**Results**
To evaluate the efficiency and effectiveness of the proposed solution, we performed an experimental evaluation with different clinical protocols of Brazilian hospitals. The evaluation explores divergent protocol perspectives applied in a mobile application. We implemented the logic of the flowchart elements in a web system for generating Android applications. We emulate the applications through Android Virtual Devices, version 2.2. The system default language is Brazilian Portuguese, but there is also a translation of the flowchart settings in English.

**Protocol 1 - Treatment of community-acquired pneumonia (CAP)**
Protocol 1 describes the treatment suggestions of the CAP through a scoring system, classifying them into 5 treatment possibilities: outpatient, with a lethality of 0.4%; Outpatient clinic, with 0.7% lethality; Hospital brief; Hospital, with lethality of 8.5%; and hospital with lethality 31.5%. In addition, in case of hospital treatments, we verify the need for intensive care unit (ICU). In all other cases, we verify the probability of specific germs and thus the appropriate prescription of drugs by doctors to fight the patient's illness happen. Subsequently, we realize the specific diagnosis of the pathogen. According to the documentation of protocol 1, in this situation, it is possible to transcribe in the proposed system all procedures, and mainly the decision logic. In this example, in the clinical decision element, the punctuation system and decisions by means of questions stand out.

Figure 1 illustrates the scoring system configuration where the user describes:

- **The segment of characteristics** - text that serves to structure and visually order the characteristics and their scores. A scoring system can have multiple segments, created dynamically by the left button "New Segment".
- **Number of characteristics** - To create dynamically rows in the table to describe the characteristic and its corresponding punctuation.

Later the creation of the configuration of the characteristics and their scores. The user must sort the result ranges. The number of result classifications indicated the limit of associations that the decision element might have. Figure 2 illustrates this process.
Figure 2 – Example of setting the result ranges for the scoring system.

In the cases of clinical decision by question, the user is only responsible for verbatim informing the type of inquiry. The proposed system of the possibility of inserting an image to assist the physician in the inspection, as shown in Figure 3. However, this type of clinical decision can only be associated with two elements: one corresponding to the positive flow and the other to the negative flow.

Figure 3 – Example of configuration of the decision by question.

The application generated automatically through the flowchart has 16 screens, which reflect each element drawn. The flow of the screens is static except for the decision elements that require user interaction to point the next path. Figure 5 shows examples of each element used in the flowchart. Figure 5 [1] shows the characteristics of the scoring system. In 5 [2] a decision by question.

Figure 4 – Protocol 1 flowchart.

Figure 5 – Examples of graphical interfaces generated for each type of flowchart element.

Protocol 2 - Management of infectious complications in severe acute pancreatitis

Unlike protocol 1 that explores a consolidated scoring system, we present the protocol 2 as a more explanatory document on the management of infectious complications in severe acute pancreatitis. In this way, the service process was widely used to structure the information in the application. Figure 6 illustrates the configuration of this element, in which it requires only: title, description and optionally image to elucidate some of the procedure.

In the example presented, we structure the flowchart as shown in Figure 4. The transcription of all protocol 2 information in the system, according to all the necessary configurations, took approximately 35 minutes. We use 1 clinical condition (Pneumonia acquired in the community); 4 elements of clinical decision, being a scoring system and three questions; 11 service processes; and a conclusion.

In the example presented, we structure the flowchart as shown in Figure 4. The transcription of all protocol 2 information in the system, according to all the necessary configurations, took approximately 35 minutes. We use 1 clinical condition (Pneumonia acquired in the community); 4 elements of clinical decision, being a scoring system and three questions; 11 service processes; and a conclusion.
Conclusion

One of the ways to structure the protocol information is the algorithm. By means of flowcharts, it is possible to graph the logic of algorithms. In this work, we explored this characteristic of clinical protocols allied to the possible standard of many applications of clinical decision system. Thus, joining these aspects proposed a way to create generic mobile applications for health professionals, without the need for coding.

We obtained the experimental results through real clinical protocols. Due to the limitation of space, it is not possible to demonstrate all proposed features, however, for the examples presented it was possible to transcribe the information as a flowchart in an easy way. Due to the simplicity of the construction of flowcharts, the usability of the system becomes high, that is, there are no ambiguous interpretations for the elements or complicated technical configurations. In addition, the cost of development is quite low. Moreover, from the construction of the project, we realize the creation of an executable android file, without the user having to install any tools.

The generated android applications showed a simple graphical interface, but perfectly usable and correct logic according to the specification in the flowchart, which demonstrates the feasibility of the proposed structure. As future work, we aim to apply improvements in this project.

Abstract

In the United Arab Emirates (UAE), health services have developed greatly in the past 40 years. To ensure they continue to meet the needs of the population, innovation and change are required including investment in a strong e-Health infrastructure with a single transferrable electronic patient record. In this paper, we report on the Middle East Electronic Medical Record Adoption Model (EMRAM). Between 2011-2016, the number of participating hospitals has increased from 23 to 33. Currently, while 20/33 of hospitals are at Stage 2 or less, 10/33 have reached Stage 5. Also Dubai’s median EMRAM score in 2016 (2.5) was higher than the scores reported from Australia (2.2), New Zealand (2.3), Malaysia (0.06), the Philippines (0.06) and Thailand (0.5). EMRAM has allowed the tracking of the progress being made by healthcare facilities in Dubai towards upgrading their information technology infrastructure and the introduction of electronic medical records.

Keywords:
Electronic Health Records, Health Services, Benchmarking

Introduction

A feature of health systems throughout the world over the past 20 years has been the increased use and reliance on Information and Communications Technology (ICT). Also called Health Information Technology (HIT) or eHealth, these developments are being pursued because of their potential to transform the delivery of health care by making it safer, more effective, and more efficient.

The application of ICT in health can be seen in various forms but one of the most recognizable is the Electronic Medical Record (EMR) or Electronic Health Record (EHR). Generally the EMR comprises a hardware and software platform that supports a dataset on each patient and which allows tests and treatments to be ordered and progress to be documented. More complex systems will support clinical decisionmaking and will allow information to be shared and reported. The EMR is a key part of a health information system (HIS) along with other subsystems such as human resources and finance [1].

Often the terms EMR and EHR are used interchangeably but there are important differences. The EMR is an organization-centric system that manages patient medical records from different sources that are used during a patient’s care (diagnosis, treatment, lab tests, imaging, medication) while an EHR system is “inter-organization”, connecting several EMRs for the purpose of sharing information among the owners of those EMRs [2].

The goal of the EMR is a clinical environment that is paper-free. EMR systems are found at all levels from primary to continuing care and in all specialties. They vary in size and complexity from those serving a single doctor’s office to systems involving groups of hospitals, clinics and other service providers. EMR systems have been extensively researched and a number of different research themes have emerged.

The installation of an EMR system is usually an expensive investment and early researchers focused on the net benefits in terms of cost saving and improved outcomes. In one tertiary hospital in a low-income country, EMR reduced length of stay, transcription times and laboratory costs resulting in a net benefit over five years of US$ 613,681 [3]. In the United States (US), in an outpatient setting the introduction of EMR was estimated to have resulted in reductions in spending and increases in revenue of more than US$ 952,000 compared with the year before implementation [4]. Also in the US, in a primary care setting, the net benefits from using EMR over a 5-year period was US$ 86,400 for each provider due to savings in drug expenditures, better use of radiology tests, better capture of charges and decreased billing errors [5]. Implementing an EMR system at a general hospital in China produced a net benefit over a six-year period of US$ 559,025 from a reduction in staff engaged in the creation of new patient records, fewer adverse drug events and dose errors, improved charge capture and decreased billing errors [6]. With respect to improved outcomes, a randomized clinical trial of an EMR-based clinical decision support system for diabetes showed that patients in the intervention group had significantly better diabetes control with increases in lifetime quality-adjusted life years (QALY) at a cost of US$ 3,017 per QALY [7]. In a US trauma center, EMR increased attending surgeons’ involvement in patient care, leading to increases in revenue and a reduction in hospital mortality [8]. Research has also focused on the implementation of EMR systems as this can be problematic. The successful implementation of an EMR system in a large Swedish teaching hospital was dependent on factors relating to the system of choice, clinician involvement, a realistic timetable and a willingness to change [9].

As the literature on the net benefits of EMR has accumulated, a number of systematic reviews have been published. The conclusions of these reviews have been mixed. One review found that while EMR may improve user and patient satisfaction, their impact on patient outcomes and quality of care was inconclusive [10]. A landmark report following an extensive review of the published literature on the benefits and
costs of EMR concluded that, while in individual pilot sites there was clear evidence that health care had been made safer, more effective and more efficient, the findings were not generalizable to other settings [11]. In particular there was a lack of knowledge about what specific systems and implementation methods should be adopted. Much of the positive evidence came from bespoke systems developed at academic medical centers or in very large health systems [12].

In many countries and in the US in particular the implementation of EMR is seen as a solution for the increasing costs of health care and as such has become a strategic goal [13]. In the US, the 2009 Health Information Technology for Economic and Clinical Health (HITECH) Act allows for incentive payments to increase adoption of EMR systems [14]. To qualify for these payments physicians must have “certified” or approved EMR systems and must be using them in a specially defined way, known as “meaningful use”, which includes at a minimum e-prescribing and electronic exchange of health information to improve quality. This requirement has led to considerable new research efforts to assess the proportion of providers that are achieving meaningful use and the characteristics of those that have done so [15]. Annual surveys are carried out and EMR adoption rates are published as performance indicators. Commercial and non-profit agencies have been established to which subscribers can report their progress on EMR implementation and thereby benchmark their performance indicators. Commercial and non-profit agencies have been established to which subscribers can report their progress on EMR implementation and thereby benchmark their performance indicators. The DHA strategy is to develop efficient, high quality and accessible healthcare services for its population, and to achieve this it focuses on three critical areas: care delivery redesign, payment incentives and patient engagement. It does this in partnership with regulators, payers, providers and consumers, and the need to connect these health system players together means that ICT and the management of medical information will play a key part in the delivery of the strategy [22, 23]. The potential of timely and accurate health information to improve population and individual health is clear [24]. However, the fragmentation of health information systems in the UAE is a challenge and leaders and decision-makers in the healthcare field often lack appreciation of the benefits of timely and accurate data [25]. Like many other countries Dubai has therefore developed an eHealth strategic plan to accommodate the changing role of ICT in improving health system performance and overcoming the current challenges. The Health Data and Information Analysis Department (HIDIAD) is a directorate of DHA which focuses on both operational and strategic aspects of eHealth. In addition to providing decision makers in DHA and other government departments with health data for health system management, it also leads in the development and implementation of the strategic eHealth plan for Dubai. The purpose of this paper is to review how far healthcare organizations in Dubai have progressed in their automation journey from paper-based to paper-less health records management and the adoption of the Electronic Medical Record.

**Methods**

In this study we make use of data from the **Middle East EMR Adoption Model (EMRAM)**, a self-reported survey tool that has been developed in a partnership between HIDIAD and HIMSS Analytics, a global health IT organization [26]. Participants, comprising public and private hospitals in Dubai, submit their data by means of the EMRAM web-based tool and are then ranked at one of eight stages which cover the spectrum of EHR implementation from stage zero (a paper-based environment) to stage seven (an environment that is paper-free). Participants are also given an overall **EMRAM Score** which combines the current stage with credit for partially achieving higher stage applications. The requirements of each stage are shown in Table 1. HIMSS and HIDIAD teams are responsible for setting up the EMRAM cycle or data collection round. They also follow up with participants to make sure that they complete the survey on time and to the required standards. The teams also conduct validation procedures to ensure the eligibility of participants who are ranked at stage five or above; these include site visits and telephone contact with chief information officers (CIO). Occasionally contact is required with software vendors involved in establishing or upgrading participants’ EMR systems. Data collection rounds have taken place in 2011, 2012, 2013, and 2014, 2015 and 2016 (quarter 2).

**Results**

All public and private hospitals in Dubai are required to participate so the response rate is 100% for each data collection round. During the five-year period 2011-2016 the number of participating hospitals has increased from 23 to 33 (because new facilities have opened). In 2011, 21/23 (90%) hospitals were at Stage 2 or less and no hospitals were at Stage 5. Currently (2016, quarter 2), while 20/33 (60%) of hospitals are at Stage 2 or less, 10/33 (30%) have reached Stage 5 (Table 1). Between 2011 and 2016 the median EMRAM score increased from 1.2 to 2.6 and the proportion of hospitals achieving at least Stage 2 increased from 40% to 91%. This is important because Stage 2 is the minimum EMRAM stage required by Dubai Health Authority before a hospital can be considered for new facilities have opened. In 2011, 21/23 (90%) hospitals were at Stage 2 or less and no hospitals were at Stage 5. Currently (2016, quarter 2), while 20/33 (60%) of hospitals are at Stage 2 or less, 10/33 (30%) have reached Stage 5 (Table 1). Between 2011 and 2016 the median EMRAM score increased from 1.2 to 2.6 and the proportion of hospitals achieving at least Stage 2 increased from 40% to 91%. This is important because Stage 2 is the minimum EMRAM stage required by Dubai Health Authority before a hospital can be considered for
Score of 6.0 and has been nominated for Stage 6. Ratification of this status is awaited.

Discussion

The ultimate purpose of tracking EMR adoption among public and private sector healthcare providers is to effectively support the implementation of e-health capability. The results of Dubai EMRAM has shown that a substantial number of hospitals in the Emirate are making good progress with their automation journey. This could highlight the educational value of EMRAM in raising awareness of EMR implementation and fostering support for e-health capacity building.

The EMRAM staged methodology along with the survey results have allowed DHA to devise an evidence-based dissemination plan for the Health Information Exchange (HIE) platform. Based on the current EMRAM situation and the measured progress, DHA has set Stage 2 as the minimum requirement for healthcare facilities who wish to join HIE. Additionally, DHA has outlined a plan to leverage all facilities to stage 6 and to be able to effectively engage with the fully-fledged HIE platform which will be completed by the end of 2016. By that time, all patients in Dubai will enjoy continuity of care no matter which healthcare facilities they visit.

It is notable that 30% of Dubai hospitals have reached Stage 5 but only one (having attained an EMRAM score of six) has been nominated for Stage 6. Stage 6 is among the most difficult to achieve because of the technical requirements for closed loop medication administration. Also, the stages above stage 5 have the highest impact on clinicians’ workload and so require very careful implementation to ensure patient care is not disrupted. These are also the stages that have the greatest potential for return on investment, so for Dubai hospitals, as they contemplate the move to Stage 6, the future will be both challenging and rewarding.

The EMRAM surveys have the potential to improve the relationship between chief information officers (CIO) and chief executive officers (CEO). In our opinion there are three reasons for this improvement: CIOs become able to clearly communicate the hospital automation situation with international and local benchmarks; both parties receive expert third-party feedback and assistance (from HIMSS Analytics) on how to improve their automation using tools such as gap analysis; and finally CEOs are able to exploit their hospitals’ automation achievement in promoting services and winning market share.

In addition to tracking EMR implementation, EMRAM data has also allowed the benchmarking of Dubai hospitals against those in other countries with comparable health systems that participate in the HIMSS scheme. Dubai’s median EMRAM score in 2016 (2.5) was higher than the scores reported from Australia (2.2), New Zealand (2.3), Malaysia (0.06), the Philippines (0.06) and Thailand (0.5). When using the “proportion of hospitals at each EMRAM stage” as the comparator, Dubai’s performance is similar to that of Spain and Italy but exceeds Germany’s. Compared to neighbor Saudi Arabia, the mean EMRAM score is similar but Dubai has a greater proportion of hospitals at Stage 5, albeit a smaller proportion at Stage 3.

There are limitations to the use of EMRAM. Firstly, EMRAM surveys do not report the expected improvements in achieved clinical outcomes within participating facilities which could follow the technological advances that are being made. Secondly, the self-reported approach is open to error unless validation procedures are carried out. These are resource intensive. Finally, from the eHealth planning point of view, questions seeking information about EMR integration capabilities within the survey are limited. To combat this, DHA uses a supplementary set of data collection to bridge this information gap.

Conclusion

Conducting EMRAM surveys within an active social network that comprises CIOs of Dubai’s public and private hospitals has created a healthy environment for engagement between leading healthcare providers and the main healthcare regulator in the
Emirate, namely DHA. DHA has set standards for eHealth capacity, which hospitals are increasingly achieving. The goal is that all hospitals will have the capacity to join the Dubai Health Information Exchange so that health information will be shared between health providers to improve continuity of care, clinical outcomes and the patient experience.

A Collaborative Evaluation Framework for Biometric Connected Devices in Healthcare

Troskah Farnia, Marie Christine Jaulet, Guillaume Marchand, and Mobin Yasinib

*Department of Medical Informatics and Knowledge Engineering in e-Health, University Paris 6, Paris, France
bDepartment of Research and Development, DMD Santé, Paris, France

Abstract
A large number of biometric connected devices are currently available with a variety of designs. Healthcare users cannot easily choose the reliable ones that correspond to their healthcare problems. The existing evaluation methods do not consider at the same time aspects of connectivity and healthcare usage. In this study, a collaborative evaluation framework for biometric connected devices in healthcare usage is proposed. This framework contains six dimensions: medical validity, technical reliability, usability, ergonomy, legal compliance, and accuracy of measurements. In a first step, these dimensions were assessed by designing a self administered questionnaire answered by the stakeholders (patients, health professionals, payers, and manufacturers). A case study was then carried out in a second step to test this framework in a project of telemonitoring for heart failure patients. The results are in favor of the efficiency of the proposed framework as a decision making tool in healthcare usage.

Keywords:
Telemedicine; Decision Making; Delivery of Health Care

Introduction
The demand for wearable medical devices and remote patient monitoring systems is anticipated to increase over the years [1]. The wearable medical devices are a subset of connected devices. There is not a standard definition for connected devices [2]. The variation and the number of these connected devices are increasing to a predicted 50 billion devices by 2020, that is to say six times the human population [3]. Therefore, to decide and select the appropriate biometric connected devices that fit the healthcare user requirements and fully interoperable have become a critical issue. A comprehensive evaluation framework could help users to make better choices. To the best of our knowledge, there does not exist a comprehensive evaluation framework that evaluates and recommends specifically the biometric connected devices for various healthcare usages. There are just, some of these devices that have approved by CE medical mark. CE mark is a legal requirement to place a device on the market in European Union. CE mark does not present a holistic evaluation framework that covers all areas of assessment. It assesses particularly the quality, safety and reliability of the connected devices that may facilitate the ordering of these devices. However, there are different evaluation frameworks in telehealth and information communication technology (ICT) in healthcare such as: CHEF [4], GEMSA [5], MAST [6], KDS [7], CHEATS [8], TEMSED [9], 3Dimensions [10] and ASSIST [11]. They introduce other assessment areas that could be complementary of CE mark assessment areas. Each evaluation framework provides a series of dimensions. Buccoliero [12] mentioned that the main ICT evaluation dimensions are stakeholders’ point of views, costs, intangible corporate benefits and social benefits. However, the diverse telehealth evaluation frameworks cited above mention more issues: clinical, economical, technical, organizational and social as they are listed chronologically in the Table 1. However, the legal, educational and ergonomic aspects have not been much studied in these evaluation frameworks. These frameworks were applied in the various similar services including tele-consultation, tele-expertise, connected health ecosystem and elderly telehealth.

In this study, the monitoring devices that collect and transfer the physiological data are considered as biometric connected devices. Inspired by these evaluation frameworks, the main objective of this study is to construct an evaluation framework in collaboration with service users for biometric connected devices in health usage.

Methods
In order to design an evaluation framework for connected devices addressed to healthcare usage, the main evaluation dimensions were selected according to telehealth evaluation frameworks in Table 1. This selection was established by an e-health expert group including two physicians (one of them also in evaluation of mobile health applications), one key opinion leader in telemedicine and health information systems, and one industrial engineer. This group defined the criteria for each dimension. Once the criteria had been developed, they were
integrated into a self administered questionnaire. There is one questionnaire for each evaluator profile (stakeholders: patient, health professional, service manager, etc.). Each questionnaire covers all dimensions for the targeted evaluator. This questionnaire was constructed in a collaborative way by various working sessions within the working group. Each criterion was then scored by each member of the working group according to its importance (from 1 to 5). The average score for each criterion determined the final importance index of each criterion. Some questions are adressed to users that include patients and healthcare professionals, other questions are adressed to service manager, payers (for the cases where users are not the payers) and device manufacturers that include managers and persons in charge of development and technical issues.

In order to quantify the qualitative answers of the questions, a score from 1 to 4 was assigned to each answer. Score “4” reflects the most favorable and satisfactory answer to the question, while score “1” is the most unfavorable response. For example, the question “Is this device easy to use ?” was assumed by a grid from 1 to 4, the score 4 is allocated if the device is very easy to use. On the contrary, the score 1 is chosen if the device is too hard to use.

The final score was reported (we decided with the experts to set the score from 1 to 20) for each biometric connected device. It was calculated by the following equation (Eq. (1)):

\[
\text{Connected biometric device score} = 20 \times \frac{\sum (\text{importance index} \times \text{the average score given by the evaluators})}{\sum (\text{importance index} \times \text{maximum question score})}
\]

This equation was used for five dimensions medical validity, technical reliability, usability, ergonomy and legal compliance. The sixth dimension “medical accuracy” was measured by the comparison of the error rate between the biometric connected devices and the existing validated professional medical devices. For example, the accuracy of the biometric connected “scale” was given by a number of measurements on the connected scale and at the same time on a validated and routinely used professional medical scale. The error rate was measured for each measurement and the average of these error rates were mentioned as the error rate of connected scale. For example, if the weight measured by the professional scale is 70.5 Kg and the average mesure with the connected scale is 70.9 Kg, there is an absolute error of 0.4 and the percentage of error rate is 0.57 calculated by the following equation (Eq. (2)):

\[
\frac{(a - b) \times 100}{b} = \frac{(70.9 - 70.5) \times 100}{70.5} = 0.57
\]

This example concerns one user. The accuracy of the scale (percentage of error rates) is the average of at least 10 error rate percentages related to 10 users with various range of body weights.

To start a collaboration work and adapt the evaluation framework with the specific users’ context, a case study in a telemonitoring project for patients suffering from heart failure was carried out. This case study required another working group including two cardiologists, two nurses working in a cardiac service and one computer engineer. Various working sessions were organized to adapt the series of questions to heart failure patient use cases. 28 patients and 6 healthcare professionals participated to this case study by answering the questionnaire. They have been trained to use the biometric connected devices and they have used them during one week. The connected devices included scale, blood pressure monitor, oximeter and pedometer. Two connected device manufacturers were selected for this test. For confidentiality reasons, the names of manufacturers were replaced by the symbols of X and Y. Other stakeholders of the project (project manager, device manufacturers) have also answered their dedicated questionnaires. The final score of each connected device was calculated from all responses of questionnaire.

To assess the accuracy aspect of biometric connected devices, we compared them with professional healthcare devices. Two nurses working in a cardiac service realized 45 measurements by each connected and professional devices. For each obtained measurement using two devices (connected and professional), the error rate was calculated. At the end of this process, the average of the error rates was shown as the error rate of the connected device.

There is no equivalent professional devices to measure physical activities. Therefore, the accuracy of pedometer has been measured by two physiotherapists riding on a treadmill with three speed levels.

### Results

Six main evaluation dimensions were defined by the working group. For each dimension, various criteria were developed. Some examples of these criteria and the stakeholders to whom the criteria addressed are illustrated in Table 2.

Evaluation dimensions are explained as follows:

**Medical validity:** It contains a series of questions that will be answered by the health professionals, payers and managers of service. It integrates many aspects: concordance with medical guidelines (including situations in which the devices are most useful, for example: wrist blood pressure monitors are not recommended unless the patient is overweight), cost/profit and national and regional policies.

**Technical reliability:** It explains the device characteristics, connectivity and maintenance requisites. The questions of this dimension will be answered by device manufacturers and service managers.

**Usability:** It evaluates the motivation, satisfaction, acceptability and technical knowledge level of users in using the connected devices. The users are the patients and healthcare professionals.
professionals, consequently they answer the related questions in this dimension.

**Ergonomy:** It evaluates the users’ experiences in guidance (how the device guides the users for using it), legibility and workload (how the use of the device adds a workload to the users). The users are the evaluators of this dimension.

**Legal compliance:** It verifies the regulatory obligations and personal data privacy and security aspects. The most skilled persons who answered the related questions of this dimension are device manufacturers and service managers.

**Medical measurement accuracy:** Basically, the connected devices are manufactured for public and wellness use. The comparison between these connected devices and the professional validated medical devices that are used routinely by healthcare professionals allows to verify the accuracy of measures for connected devices in medical usage at patient’s home.

In total, 49 questions were extracted from various criteria in all dimensions. Table 3 represents the number of questions in each dimension.

**Case study:**

This evaluation framework was tested in the development phase of a telemonitoring project for heart failure patients. Telemonitoring users (patients and healthcare professionals), manager and connected devices manufacturers answered the questionnaire for 4 connected devices. The final score of each connected device is presented in figure 1.

The final score of each connected device is obtained by the results of the questionnaire including five-evaluation dimensions: medical validity, technical reliability, usability, ergonomy and legal compliance.

Figure 2 shows the error rate percentage of three connected devices: scale, blood pressure monitor and oximeter.

The diastolic blood pressure error rate is very high (more than 10%), consequently this measurement will be less accurate. However, the weight measurements given by the two manufacturers' scales are very accurate (with almost 0% error rate).

Accuracy tests with pedometers were performed at three different speeds (3km/h, 4km/h and 5km/h). Figure 3 shows a very high error rate as 3km/h speed.

The choice of pedometer depends on pedometer users’ speed. For heart failure patients who walk maximum with 3km/h speed, both pedometers were not considered to be accurate.

According to these tests, the accuracy of the pedometers depends strongly on their wearing position. The pedometers were put in the pocket, on the belt, and on the wrist. Figure 4 shows that the pocket position has less error rate than the other positions.
The final choice of the biometric connected health devices depends on their final score and their accuracy test. In this case study, the Scale of manufacturer X, the oximeter and blood pressure monitor of manufacturer Y obtained the most suitable score to the context of telemonitoring for heart failure patients.

Discussion

In this study, we proposed a collaborative evaluation framework for biometric connected devices in healthcare usage. This framework includes six dimensions that help users to make the best decision and choose the best devices among the large varieties that are adapted to their usage in a simple way. This framework can be easily adapted to different use cases. This process evaluation allows the manufacturers to better know their connected devices before embarking on the legal CE procedure.

In the literature we can find various studies on mobile health applications and mobile devices evaluation [13,14]. Our study specifically addressed the evaluation of the connected biometric devices and it involves all stakeholders in the evaluation process. It explains in details each criterion and the way to measure them by the scoring method. It also considers more specifically the accuracy of the measures that has not yet been mentioned in previous published studies.

The assessment of a connected device could not be carried out without the evaluation of the accompanied mobile application. This framework describes the dimensions and criteria regarding the connected device itself. An evaluation process for the accompanied mobile application should be added to this framework to assess the quality of the connected device in all aspects. An example of mHealth app assessment process that could be used beside this framework is mHealth Quality [13].

The final score showed that there is no great difference between the scale and blood pressure monitor of two manufacturers. However, the difference is considerable for oximeter and pedometer. Concerning pedometers, high error rates were seen in both analyzed devices. We have tested our framework only in two brands. This can limit the results of our analysis. However, these two brands were selected among the market leaders for connected biometric devices. Further research is needed to validate our results with a larger scale of connected devices brands and in the context of a broader chronic diseases.

This framework could be used in a broader multidimensional study for medical remote monitoring projects in chronic diseases. Another utility of this evaluation framework could provide the criteria to create a certification process for biometric connected health devices. The certification process needs to define some of the criteria as mandatory and set up the cut off score above which the devices could be certified. mHealth Quality [13] is actually working on this framework and use it in their certification process for connected biometric devices.

Conclusion

The use of wearable medical devices is certainly growing. Therefore, an individual is facing a jungle of connected items including very good devices as well as dangerous ones. A wide selection of mHealth devices with a real diversity of usages provides the opportunity to do almost everything in every medical specialty. However, this diversity prevents a “one size fits all” approach to ensuring the quality of these devices and information security. Exploring and creating adapted criteria to each device for providing individualized assessment method based on the provided functions is an important issue of the future research.

The results of this study show that there is still a long way to proceed to improve the reliability of the connected biometric devices particularly in pedometers. None of the devices reached the score 15 out of 20. To use these devices in the telemonitoring system, both health professionals and patients need to trust connected biometric devices. This trust can not be gained if these devices are not reliable in all discussed dimensions.

Serious Games for Parkinson's Disease
Fine Motor Skills Rehabilitation Using Natural Interfaces

Antônio Augusto Folettoa, Marcos Cordeiro d’Ornellasb, Ana Lucia Cervi Pradob

Laboratório de Computação Aplicada, Universidade Federal de Santa Maria, Santa Maria, RS, Brazil, Hospital Universitário de Santa Maria, Universidade Federal de Santa Maria, Santa Maria, RS, Brazil

Abstract
Parkinson's Disease rehabilitation can be long and boring being difficult to maintain patient engagement on therapy programs. Novel technologies are allowing computer games to be played through natural interfaces. This paper presents the development and assessment of a system of serious games for fine motor skills rehabilitation using natural interfaces. The games were assessed through a questionnaire that evaluated the game experience through seven components: immersion, flow, competence, tension, challenge and positive and negative affect. In addition, a conceptual framework for development of serious games for fine motor skills rehabilitation was proposed. The results from the questionnaire suggested that the player experience was positive on all components assessed. Also, player experience between the three games was statistically the same, implying that the games can be used with consistency in a physical therapy rehabilitation program.

Keywords:
Computer Games; Motor Skills; Rehabilitation

Introduction
Parkinson’s Disease (PD) is one of the most common neurodegenerative disorders, affecting round 1% of world population over 60 years old [1]. Among all the symptoms related to the disease, tremors, movement stiffness, lack of attention and postural instability can be highlighted. Tremors can be very severe, impairing the hands and fine motor skills of the subject. Fine motor skills represent muscle, bones and nerves coordination to execute accurate movements. These movements use hand and fingers to grab, manipulate objects and tools like when using a pencil or scissors. These fine skills can be impaired due to lesions, diseases, or even stroke; although spine, nerve, or muscle injuries might cause some disturbance as well. Subjects with PD can show difficulty to speak, eat or write because they lost some of their fine motor control [2].

Most treatments for PD are based on administration of drugs, but there is also recovery and rehabilitation by physical therapy programs. Physical therapy programs help to contain symptoms of the disease throughout physical exercises. These exercises can stimulate the brain allowing neurons to create new connections to fulfill difficulties that were imposed by the disease [3]. These therapy programs can take a long time, as the disease has no cure, and the exercises proposed can be boring and repetitive [4]. That can contribute to a drop on patient adherence to treatment or even evasion from the therapy program.

Technology can bring more to people's lives than simply improve performance on doing tasks, it can provide joy and richness, improving the experience. A Serious Game (SG), is a game that can transmit a message, knowledge, skill, or a content to the player. In addition, it might improve the player experience through different kinds of interaction and on different contexts, e.g., health, training and education.

The main goal of serious games for health is to provide knowledge or enhance player skills as any other serious game but, in this case, it must serve a medical purpose. Serious games are being used in many health fields, from exergaming to surgery simulators. Videogames like Wii Fit and Kinect Sports have mainstreamed the genre among physical therapists. However, these games are not built for therapy and individuals need physiotherapy programs tailored to their needs. Also, this genre of games should have more flexibility to allow the therapy to be more personalized according to the subject’s capacity and avoid further lesions [5].

Interaction in traditional games are mainly based on mouse and keyboard or joysticks. As computers decreased in size and cost and have growth in processing power, new platforms and interactions were developed. The possibility to create and interact with virtual worlds the same way we interact with physical objects has motivated many researchers to develop new technologies. In consequence, novel technologies that can track cerebral waves, eye movement, body movement, etc. are being developed. Movement sensors like the Microsoft Kinect or the Leap Motion allow the creation of natural interfaces. A natural interface is not an interface that is natural, but it makes the user perceive and use as natural. It is not a feature of a software or device to have a natural interface. The user must feel as natural while using that interface, through a natural interaction, using day-to-day gestures and movements.

Even when people with PD have access to a rehabilitation program with quality and qualified professionals, the program may be long and become unpleasant. In some cases, these individuals, may present lack of motivation during the program due to its degree of repeatability that causes tedium [4,6,7]. In addition, cases of depression and dementia on PD can withdraw these individuals from special care. The use of games has proved to be a good way to fight lack of motivation that results from repetitive exercises on therapy programs [8]. The works of [3, 7, 9, 10] are some that have explored development of serious games for health using movement sensors to help therapies for motor disorders. Although, there seems to be a lack of works focused on fine motor skills rehabilitation using hand movement sensors like Leap Motion. As an off the shelf device that can detect hand movements with low cost, Leap Motion should be explored as a tool for hand rehabilitation [6].

This paper describes the assessment of player experience in a system of serious games for health using natural interfaces. The games were tailored to help therapists on fine motor skills rehabilitation programs. A one-way ANOVA is used to analyze
if all the prototypes can provide the same game experience regarding immersion, flow, competence, positive affect, negative affect, tension and challenge. Additionally, based on the development of three prototypes, we propose a conceptual framework for development of serious games for motor skills rehabilitation using the Leap Motion device.

**Leap Motion**

The Leap Motion is a USB device that can detect hand and finger movements in a 3D environment with high precision and performance. The device is relatively small and robust, with a width of 80mm, height of 12.7mm and depth of 30mm (Figure 1). It has three infra-red emitters and two infra-red (IR) sensors inside. Its field of view (FOV) is round 61cm$^3$ and it is shaped like a hemisphere. According to its website, the Leap Motion can track hand movements with an accuracy of 1/100mm, but [11] has found an accuracy of 0.7mm when tracking non-linear movements executed by a robotic hand. Nevertheless, it has higher accuracy than other devices on the market, e.g. Microsoft Kinect.

![Figure 1 – A Representation of the Leap Motion Hardware Structure, Showing External Dimensions, Infra-Red Emitters and Sensor Positions [11].](image)

**Unity Game Engine**

The Unity Game Engine was chosen mainly, because of its collection of tools and assets that allow rapid prototyping. Also, there is additional effort by Leap Motion developers to create bootstraps and tools for Unity. There is more documentation and also more graphic assets (prefabs) and scripts to use on prototypes. Moreover, Unity is the most used game engine by game developers according to data found on their public relations page.

**Conceptual Framework**

It is proposed a conceptual framework for the development of serious games with focus on motor skills rehabilitation using Leap Motion. This framework was based on a common architecture used to develop three prototypes. Basically, it has five layers: User layer, Input/Output layer, Game Engine layer, Database layer and Web Application layer. The framework proposed is illustrated in Figure 2.

![Figure 2 – Representation of a Framework for Development of Serious Games for Motor Skills Rehabilitation](image)

The **User layer** is composed by the actors of the system: the player and the therapist. Both of the user profiles interact with the game through the I/O layer, but only the therapist should use the Application layer.

The I/O layer is responsible for the interaction/interface with the user. It is composed by hardware elements, like the Leap Motion – responsible to provide hand and finger tracking data, Mouse and Keyboard, Sound and Display.

The Game Engine layer is responsible for all the game logic, since handling input/output to rendering the game. Usually, this can be done by a real game engine as Unity or Unreal. The components inside this layer are: Leap Controller, it process the tracking raw data to be consumed by other components and objects; Gesture Controller, it checks tracking data for gestures and control gesture actions like grabbing or pinching; Game Controller, responsible for game management like scores, times, rules, etc.; GUI Controller, it manages the graphical interface elements of the game; gathers information from Game Controller and Database to output relevant information for the player and therapist; Game Settings, it manages the game adjustments that can be controlled by the therapist such as time counter, spawn speed, gesture sensitivity, number of objects to be spawn, etc.; User Controller, it is responsible for user data, such as user profile, user therapy program and sessions; Database Controller, handles the persistence layer of the game serializing information and storing in the database.

The **Database layer** is responsible for storing the data that is collected after each session. The Application layer can be represented by a Web Application that consumes data stored on the database to provide insights and report patient progress throughout the program.

**Prototypes**

Three game prototypes were developed based on movements that were observed during rehabilitation sessions at the Rehabilitation unit of Hospital Universitário de Santa Maria (HUSM). In addition, physical therapy professors and professionals provided insights about fine motor skill exercises. These first prototypes were pitched to therapists, a game development professor and a design professor. Based on the considerations provided by those professionals, we iterated over the prototypes and refined them.
The prototypes were developed based on nature and farm life. This theme was chosen because the target audience is significantly composed by elders. The current generation of elders has at least some relation with nature and probably encountered a rural environment when young. Also, each game had a different metaphor that was chosen according to the gesture that was required to play in order to create affordance. The interaction has to make sense to the player, the gesture and the metaphor have to complete each other.

**Game Prototype: Pinchicken**

The mechanics of Pinchicken game is, basically, to pinch eggs that appear on the ground and drop it on the right chicken nest (Figure 3). The scene is composed by three chicken nests with chickens and eggs that keep falling on the ground. When the player pinch and egg, the game will highlight only one nest to drop the egg on. When the player succeeds moving the egg to the right nest, 10 points are awarded, a sound and a visual effect are played as feedback. When it is mistakenly placed, negative sound and visual feedback are played, but no points are awarded neither subtracted. Punishing the player is not the intention, because it can affect player motivation.

![Figure 3 – Game 01: Pinchicken, Player Should use the Pinch Gesture to Grab Eggs.](image)

**Game Prototype: Finger-Hero**

The prototype Finger-Hero is based on the mechanics of a blockbuster game called "Guitar-Hero". There are 4 lanes, each one has a flower at the end with a color (green, red, blue, yellow) and a thumb opposition gesture (index, middle, ring, pinky) associated. The game will randomly spawn bees that will move towards the flowers on each respective lane. The objective is to execute the correct opposition gesture when the bee is right above the flower. For example, if there is a blue bee on the third lane, as represented in Figure 4, the player should do the thumb opposition gesture with his ring finer when the bee is exactly over the blue flower. If he succeeds, 10 points are awarded and positive sound and visual feedback are given. Else if he misses only negative sound and visual feedback are given.

![Figure 4 – Game 02: Finger-Hero, Player Should use Thumb Opposition Exercise to Play the Game.](image)

**Game Prototype: Grabduzeedo**

On Grabduzeedo the player controls a spaceship with the hand and the tractor beam can be activated and deactivated using the grab and release gestures (Figure 5). The game will spawn sheep on a platform on the right side of the screen. The objective is to abduct the sheep, closing the hand (grabbing), and moving it to the platform with fences on the left. Just open the hand to release the sheep in place. When the sheep is placed inside the fence 10 points are awarded and positive sound and visual feedbacks are given. Otherwise, negative feedback is given, but no points are awarded or subtracted from the player.

![Figure 5 – Game 03: Grabduzeedo, Player Suse the Grab Gesture to Control the Spaceship’s Tractor Beam.](image)

**Methods**

**Initial Setup**

The experiments were conducted at the Rehabilitation Unit of HUSM, on a room with enough space and climate and light control. The last is extremely important because natural infrared light that is emitted from the sun can interfere on Leap Motion’s tracking accuracy.

The setup includes a chair for the participant and desk to place the computer, the display and the Leap Motion device. The Leap motion was placed right in front of the display. Also, a camera was placed on a tripod in the corner of the room. The questionnaire and the consent form were printed in plain paper.

The game can finish when a countdown timer ends or when the player reaches a pre-defined maximum score. A time span of a minute and a half (1m30s) for each game was determined by the therapist as optimal to conduct the experiment. So, the participants had to sum the maximum points before the time ended. In addition, it was defined that the players would use only their dominant hand to play the games.

**Game Experience Questionnaire (GEQ)**

Game experience and common software experience are composed of different aspects and therefore they need to be assessed differently. The GEQ is an instrument to assess the overall game experience perceived by the player and it was proposed by [12]. They validated the questionnaire with 380 participants who played games of their own choice. The group was composed by 254 men and 120 women (6 null responses) who played games daily (29%), weekly (38%), monthly (13%), few times per year (12%) and hardly ever (8%). The instrument is composed of 4 modules: core module; in-game module; post-game module; and social module. The questions are answered using a Likert scale ranging from 0 to 4 (or from "not at all" to "extremely").

The core module has 33 questions and the result can be obtained by calculating the scores of seven components [12]: Immersion...
is related to the fantasy, aesthetics, and imagination; Flow represents the experience of losing track of time and loosing connection with the outside world; Competence express if the player was good, successful or skillful at the game; Positive affect represents if playing the game was fun or if it felt good; Negative affect is related to the player feeling bored, distracted or had mood; Tension is related to how nervous, restless or annoyed the player felt; Challenge is related to how many effort the player think he put in the game or if he felt a time pressure. The questionnaire and scoring system have some redundancies and spare items to prevent misunderstandings caused by translation. The in-game module has 14 questions (the questions are a mirror from the core module) and it is meant to be applied just after gameplay short breaks. The post-game module has 17 questions and assesses how the player felt after the whole gameplay session, its score is based on four components: positive and negative experience, tiredness and returning to reality. The social-presence module is meant for multiplayer games, aiming to understand how the player felt interacting with other player during gameplay through 17 questions.

For this study, only the core module was used. As the game sessions were short and single-player, the in-game, post-game and social-presence module were not required.

Participants

The participants were admitted for the experiment on a random and voluntary basis (with no monetary compensation) at the rehabilitation unit of HUSM. All the participants were from a physical therapy background: students, technicians, therapists and professors. Overall, we conducted the experiment with 20 healthy adults. According to [13] on a user experience or usability test only 5 people are sufficient to discover round 80% of the problems, but for quantitative purposes a number of 20 people is recommended. Also, [14] argues that most game evaluation works have a population of 11 to 20 people.

Procedure

First, all participants sat in a chair with the display and Leap Motion in front of them. They were instructed to sign the consent form needed for trials. Also, a brief explanation on how the experiment would proceed was given. Before testing with the prototypes, the participants had a time to familiarize with the device and technology. A period to feel how the device tracks the hand, how far it reaches and how to interact with it. On this step, the participant interacted freely with the Leap Motion’s built-in visualizer app.

After the participant was comfortable with the device, he proceeded to play the game. Exactly after each game had finished, the patient had to answer the questionnaire. This process was repeated for the other two games. The whole session took about 20 minutes, depending on each participant’s speed to answer the questionnaires. In addition to the questionnaires, we recorded the scores of all the participants.

In order to analyze the data, GEQ-Scores were calculated. The score for each component is determined by the arithmetical average of the answers that are related to that component on GEQ’s Manual. Then, the GEQ Scores of the games were compared with each other on every GEQ-Core component level. A one-way Analysis of Variance (ANOVA, α = 0.05) was used to verify if GEQ scores had significate variances or if the game experience was the statistically the same across each game. The research hypothesis checked with ANOVA were:

- \( H_0 \) = The overall game experience for all games is the same;
- \( H_1 \) = At least one game has a different experience;

Results

The data from 37 questions was collected from 20 participants: 11 physical therapy students (55%), 1 professor (5%), 6 professionals (30%) and 2 technicians (10%); 16 Females (80%) and 4 Males (20%); Age ranging from 20 to 45 years old. Then, the score of each GEQ-Core component was calculated for each game: competence, immersion, flow, tension, challenge, negative and positive affect; and compared. As it can be observed in Figure 6, optimal results were obtained for both positive and negative aspects of game experience for all the three games. Positive Affect, Immersion and Flow components had the best scores; Competence and Challenge presented a neutral/medium score while Tension; and Negative Affect had minimal score.

Player experience regarding Competence component resulted in statistically the same values for Game 01 (M=1.86±0.73) and Game 02 (M=1.87±0.67) and Game 03 (M=2.25±0.92). The ANOVA for all the components presented p-value superior to alpha, confirming the null hypothesis.

Discussion

It can be argued that the 'Competence' scores were positive because the games were somehow easy to play, allowing players to feel capable of completing the task. A slightly difference between values of Game 01 and Game 02 to Game 03 can be observed. That is because the gesture and interaction required to play the third game was much simpler than the others, requiring lower levels of coordination and dexterity to achieve the goal.

The best score values were from 'Positive Affect' component (Game 01 = 2.92±0.65; Game 02 = 2.78±0.85; Game 03=0.74) it represents the fun and joy experience by the player during gameplay. Also, flow (Game 01 = 2.62±0.75; Game 02 = 2.67±0.83; Game 03 = 2.6±0.92) and Immersion (Game 01 = 2.51±0.70; Game 02 = 2.66±0.66; Game 03 = 2.69±0.56) presented good values representing that the game kept the player focused, was aesthetic pleasant and that it impressed the players. It is said that a game achieved immersion and flow when the player loses track of time and has the feeling to be transported to another place.

Overall, the results obtained from analyses of GEQ data suggest that the system of serious games prototypes presented has good level of user experience and usability on all three prototypes.
Further analysis with ANOVA pointed that the game experience across the three prototypes is statistically the same. That is a positive outcome because the prototypes were designed to work as a system of serious games, not as standalone games. Hence, it is expected that the game experience of each game is similar or the same. It provides consistency for the system. This work is limited to player experience assessment. Further work should be conducted to evaluate the functionality and the validity of the games as a tool for rehabilitation. Also, there is still some space for improving on aesthetical and mechanics aspects of the game. Moreover, a web application that consumes data from database could be built to help the therapist track patient progress.

**Conclusion**

In this work, the main contributions are the development of a system of serious games for fine motor skills rehabilitation using NI. The system allows therapy sessions to be customized to patient needs, and also adding more fun and engagement. It can replace exercises that are repetitive and boring, helping to control patient evasion from therapy programs.

It is also proposed a conceptual framework for development of serious games for fine motor skills rehabilitation using Leap Motion. framework worked as expected during the development of three game prototypes.

Results obtained from the questionnaires point that the experience of the three prototypes are similar, allowing the therapist to use them on therapies with consistency. Positive components presented high scores and negative components scored near zero. Also these results can support a physical therapist to validate the system as a tool for rehabilitation of fine motor skills.

Patient Portal Adoption Rates: A Systematic Literature Review and Meta-Analysis

Paolo Fraccaro, Markel Vigo, Panagiotis Balatsoukas, Iain E. Buchan, Niels Peek, Sabine N. van der Veer

Patient portals are online services that allow people to have access to their electronic health records (EHRs) and support basic activities such as booking appointments, recording symptoms, and communicating with healthcare providers [1, 2]. They are considered a valuable instrument to engage patients in having a more active role in their care [3–8] and aid self-management [8–10]. Many patient portals are developed for people with long-term conditions [9, 11]. Patient portals are increasingly available [1, 12, 13], but their impact on health outcomes has yet to be established [14–18]. Previous systematic reviews found positive effects on patient engagement and satisfaction [14, 15, 17, 18], but evidence on the effect of patient portal use on care processes and health outcomes is conflicting [14, 15, 18]. Our understanding of this variation in impact is currently limited [14, 15]. This might be related to the fact that published evaluations tend to focus on clinical endpoints, without considering the complex process that leads to them [19, 20].

As proposed by Coiera in his ‘information value chain’ [20], for any health information system to have impact, users first need to adopt the system and effectively interact with it (step 1) in order to receive information (step 2), which might then influence their decision making (step 3). This might lead to improved care processes (step 4), and, under beneficial conditions, to better health outcomes (step 5). Although not sufficient, good results are necessary at each step to achieve eventual positive impact on clinical endpoints [20]. Following Coiera’s information value chain, evaluating adoption rates is essential for understanding the (lack of) effect of patient portals on decision making, care processes and health outcomes.

Although individual patient portal studies may have reported on adoption rates [21–23], up till now no study has summarized these rates across studies. Also, adoption rates in controlled experiments may not always translate well to a real life context [15]. This disconnect between findings from controlled and real-world experiments might partly be explained by the former being more likely to include strategies for optimizing recruitment and minimizing attrition than the latter [24]. For example, a study in primary care showed that patients in practices with a more active strategy to promote portal use were more likely to be registered users compared to those in practices with a less active or no strategy [25]. Therefore, we systematically reviewed the literature on patient portals to investigate adoption rates across individual studies, and how rates might differ between controlled and real-world experiments.

Methods

We followed the PRISMA statement [26] to design and report our systematic review and meta-analysis, where applicable.

Search strategy

We used the search strategy that we developed for a broader literature review on methodological approaches to evaluate patient portal usage, usability and effect on decision making (i.e. Coiera’s information value chain steps 1-3). We searched for English language articles in MEDLINE via Ovid and in Scopus by combining subheadings and text words for patient portals with those referring to system usage, usability, and decision-making (full searches available at [27]). The searches were performed on the 18th of July 2016.
**Selecting relevant studies**

We considered studies relevant if they:

- Evaluated patient portals, using the definition of Irizarry et al. [2]: systems providing patients with access to their EHRs, and allowing them to enter health data or share information with their healthcare providers. We excluded studies on systems only providing educational material, or online booking or secure messaging functionalities.

- Had patients, carers, or healthy volunteers from the general population as the study sample, excluding those testing the system only within the research team.

- Reported sufficient information to determine portal adoption rate in the study population. Adoption was defined as the % of eligible patients who logged in at least once or—if this information was not available—had an active account during the study period. We excluded studies that only reported other types of usage statistics (e.g. frequency of use).

- Collected data on adoption through system interaction logs. Studies retrospectively asking patients about their portal use in surveys were excluded because such data lack in objectivity [28] and are known to be affected by recall bias [19]. We also excluded studies investigating intended use.

- Were peer-reviewed original articles (including conference papers) or systematic reviews in English, while excluding conference abstracts, narrative reviews, editorials, view point papers and grey literature.

After removing the duplicates from the Ovid and Scopus searches, the principal reviewer (PF) independently screened the titles and abstracts of all studies, whereas two secondary reviewers (PB; SvdV) did 50% each. For studies considered potentially relevant, we retrieved the full papers and two reviewers independently identified those meeting our inclusion criteria. At each stage of the review process, disagreement was solved through discussion.

**Data extraction**

We built a data abstraction form on the basis of previous systematic reviews on patient portals [17, 29] and health information systems evaluations [19, 30, 31], and pilot-tested it among the authors (PF, SvdV, MV, NP). The final form included items related to: general study characteristics; study type (controlled versus real-world experiment); study population; patient portal functionalities (data access; data recording; data sharing); number of potential patient portals users; number of patients who logged in at least once or had an active account during the study period. For real-world experiments, we additionally extracted information on strategies aimed at increasing patient portal adoption.

Controlled experiments were defined as any study where patients were actively recruited to participate in research and where data were collected prospectively. This included experiments with single groups as well as those with multiple groups (with participants being allocated either randomly or non-randomly), with the number of potential users equaling the number of participants recruited into the study. In case of multiple groups, we calculated this number across groups. Real-world experiments concerned observational studies that retrospectively evaluated adoption after a patient portal had been deployed in clinical practice. In this case, the number of potential users were all eligible patients in the clinical context of interest who should have been offered access to the portal.

One author (PF) extracted the data and performed the data synthesis for all studies. Uncertainties during the data extraction process were addressed and resolved by discussion with a second member of the research team (SvdV).

**Data synthesis and analysis**

We organised results according to study type. We calculated the mean adoption rate and 95% confidence interval (CI), both overall and stratified for study type. We also conducted a random-effects meta-regression analysis to evaluate the influence of the study and patient portal characteristics on adoption rates using the metafor R package [32]. Prior to the regression analysis, we performed a logit transformation on adoption rates reported in the included studies [33]. From the meta-regression coefficients estimates, we calculated Odds Ratios (ORs) and 95% CI. Furthermore, as prescribed by Stevens et al. [33], coefficients estimates were back-transformed to the proportional scale by using the mean adoption rate across all studies as anchor value. This gave us the estimated effect of each model covariate in a study with an average adoption rate.

**Results**

Figure 1 shows the flow diagram of our screening and selection process that yielded 40 relevant studies.
**Study characteristics**

Table 1 presents the general characteristics of included studies (extracted information and the full reference for each individual study is available at [27]). We identified 24 controlled and sixteen real-world experiments. The majority of included studies were published after 2010, conducted in the United States, and had a duration of 1 to 2 years. The vast majority of patient portals under evaluation provided some kind of access to patients’ EHR as well as to data recording functionalities. Overall, the two study types had similar characteristics, with the main difference being the number of potential portal users. In particular, we found smaller numbers of potential users in controlled compared to real-world experiments, with the majority reporting values below 1,000 and above 10,000 people, respectively.

**Strategies to increase adoption in real-world experiments**

Five of sixteen (31%) real-world experiments did not report any strategy to promote adoption. The remaining eleven reported a range of strategies aimed at increasing patient portal adoption rates. In five studies, eligible patients were directly invited (i.e. via mail or staff) or provided with system credentials that they only had to activate. Four studies disseminated promotional material to raise people’s awareness of the portal via different channels, such as flyers and posters in waiting areas, directed electronic mailings or via staff. In three studies, computers were available in clinical settings for patients to access the portal. Lastly, two offered user training, one had personnel available onsite to support patients with using the portal, and one offered a help desk service.

**Patient portal adoption rates**

The overall mean adoption rate across all included studies was 52% (95% CI, 42 to 62%). When stratifying for study type, controlled experiments had a mean adoption rate of 71% (95% CI, 64 to 79%), compared to 23% (95% CI, 13 to 33%) for real-world experiments.

The results from the meta-regression are shown in Table 2. Study type was the only statistically significant covariate in the model after adjusting for all other study and patient portal characteristics. In particular, the OR for controlled versus real-world experiments was 10.8 (95% CI 3.2 to 36.3). This would translate to a difference in adoption rate of 40% (95% CI, 26 to 46%).

1) Change in adoption for a study with underlying adoption rate equal to 52% (i.e. mean value across all included studies).

2) Each of the three functionalities was included in the model as a binary variable, with ‘Data access/recording/sharing not provided’ as the reference category.

**Discussion**

**Summary of the findings**

We performed a systematic review of the literature and a meta-analysis of adoption rates of patient portals. The overall mean adoption rate was 52% (95% CI, 42 to 62%). Despite the majority of real-world experiments reporting the use of strategy to promote adoption, rates evaluated in real life were markedly lower compared to those evaluated in controlled experiments (23 and 71%, respectively); most of the other study characteristics and patient portal functionalities were similar between study types. A meta-regression analysis confirmed these findings.
Relation to other studies

Our meta-analysis is the first comprehensive, systematic review of studies reporting patient portal adoption rates. We are also the first to provide a summary statistic of adoption rates across individual studies, while quantifying the influence of study type and other characteristics on the rates reported.

Our findings complement what was found by Irizarry et al. [2]. Whereas they reported on the barriers to adoption of patient portals (i.e. involving personal characteristics, system usability, provider endorsement and security), our study provides evidence on the size of the problem of suboptimal adoption.

Our study confirms what was suggested by Giardina et al. [15] in their systematic review of randomised controlled trials (RCTs) of patient portals, who hypothesised that evaluation of adoption in clinical practice may give different results from those obtained in RCTs. Two main reasons may underly their hypothesis. First, patients who agree to participate in this type of study are generally interested in and motivated to use the patient portal [34]. Second, patients who are recruited for a research study know that their actions will be studied, which is likely to change participants’ behaviours (i.e. Hawthorne effect). Both reasons may increase the levels of adoption.

What is the meaning of the findings and what are their implications?

In the studies that we labelled real-world experiments, it was more difficult to assess the denominator than in controlled experiments. For the former, the denominator was commonly set as the largest group of patients who could have used the portal, while for the latter it was the number of patients to whom the portal was actively offered as part of the study. Due to this difference in counting, real-world experiments were more likely to have lower adoption rates, which may have resulted in our overestimating the difference between the two study types.

As prescribed by Coiera’s information value chain [20], to increase the probability of improving care processes and health outcomes we first need to ensure that the previous steps in the chain have been taken successfully. Our study showed that when deployed in a real-world context, most patient portals failed to obtain high adoption rates. It is noteworthy that our findings were based on a rather crude definition of adoption (i.e. at least one login or activated account during the study period). However, in order for patients to receive substantial information from portals that might affect their decisions, more may be required than just activating a user account or logging in only once. Furthermore, applying a more sophisticated definition of adoption (e.g. logging in multiple times over a sustained period of time) is expected to have resulted in even lower adoption rates for both study types.

Low adoption rates were obtained despite real-world experiments reporting to have used active strategies to maximise enrolment and facilitate portal use. Therefore, the problem might not only be related to if and how patient portals are promoted, but also to whether patients consider portals relevant for self-managing their condition in everyday life. In this regard, a positive example comes from Kaiser Permanente, which was the only real-world experiment obtaining high adoption rates (i.e. 62%) in a large population [35]. Kaiser Permanente is the most widely used privately owned patient portal in the world [36]. They have their patient portal at the centre of their business model. Patients, in addition to gaining access to their EHRs, can use the platform to download documents and forms necessary to use Kaiser Permanente services [35]. A previous study further showed how patient-centeredness and making information actionable are other main components of their success [37].

Limitations

This systematic review has two main limitations. First, some steps of the review process were not performed by two independent researchers. Therefore, these steps might have been more prone to errors than others; it was up to the discretion of the primary reviewer to discuss items that were less straightforward to extract and required more interpretation. Second, with 40 studies included, the meta-regression analysis might have been underpowered to detect statistically significant effects for factors other than the study type. However, as shown in Table 1, study characteristics were similar between the two types of studies; therefore we do not expect this to have influenced our results.

Conclusion

Overall, studies on patient portals found that half of the targeted population adopted the intervention. However, this number was markedly lower when evaluated in real-world experiments, with only one in four patients adopting the portal once deployed in clinical practice. Therefore, patient portals are unlikely to influence clinical endpoints in a real-world setting. Future studies in this field should focus on identifying factors and processes that positively affect adoption of patient portals in clinical practice.

E-HOSPITAL – A Digital Workbench for Hospital Operations and Services Planning Using Information Technology and Algebraic Languages

Daniel Gartner\textsuperscript{a} and Rema Padman\textsuperscript{b}

\textsuperscript{a} School of Mathematics, Cardiff University, Cardiff, Wales, United Kingdom, \textsuperscript{b} The H. John Heinz III College, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA

Abstract

In this paper, we describe the development of a unified framework and a digital workbench for the strategic, tactical and operational hospital management plan driven by information technology and analytics. The workbench can be used not only by multiple stakeholders in the healthcare delivery setting, but also for pedagogical purposes on topics such as healthcare analytics, services management, and information systems. This tool combines the three classical hierarchical decision-making levels in one integrated environment. At each level, several decision problems can be chosen. Extensions of mathematical models from the literature are presented and incorporated into the digital platform. In a case study using real-world data, we demonstrate how we used the workbench to inform strategic capacity planning decisions in a multi-hospital, multi-stakeholder setting in the United Kingdom.

Keywords: Models, Theoretical; Decision Making; Hospital Administration

Introduction

The rapidly growing patient population worldwide and the increasing demand for high-quality healthcare services are imposing severe capital, resource and human capacity constraints on hospitals. For example, one in every five Medicare beneficiaries in the United States is hospitalized at least once or multiple times per year. On the supply-side, almost 5,000 inpatient, acute-care hospitals exist nationwide that treat these beneficiaries. Of the approximately $300 billion dollars spent on the Medicare program per year, almost $100 billion is spent on inpatient services [1].

Given limited budgets, hospitals seek to treat patients efficiently and effectively in order to stay profitable. Adapting inpatient services that aim to improve the planning of hospital-wide workflows using information technology (IT), operations management (OM), and advanced data analytics (DA) techniques are some of the recent developments that we observe in healthcare delivery [13, 15, 16, 28, 29].

In this paper, we demonstrate this convergence by proposing a unified digital workbench to help multiple stakeholders to improve the planning and allocation of scarce hospital resources to improve transparency and efficiency of inpatient services. Additionally, we demonstrate the feasibility of the proposed workbench by applying it to capacity planning decisions at a multi-hospital site using a preliminary prototype implementation.

Hierarchical Modelling of Organizational Decision Making

We draw on the classical hierarchical management decision levels [2] to delineate different stakeholders’ objectives for a using our workbench at each decision-making level. A framework to break down business decisions into strategic, tactical and operational decision levels are illustrated in Figure 1 [2]. Its essential aim was to assess the environment of an organization and to adjust internal resources accordingly [11]. The model is depicted by the regular triangle shown in Figure 1.

The figure reveals that the strategic decision level covers a broad scope of unstructured problems while operational level decisions are more focused and structured. This is a clear approach to show how healthcare management decisions can be organized. When strategic decisions are performed, decision makers focus on, for example, patient groups, rather than an individual patient which is the focus of operational scheduling decisions. Despite its development more than 50 years ago, the framework presented in [2] is still widely accepted in decision support systems (DSS) research, as demonstrated in [3]. By breaking down DSS research literature into the classical hierarchies, their work reveals that the majority of business problems in DSS design science research have focused on the operational level. In contrast, our E-HOSPITAL workbench combines all levels in one digital platform.

Stakeholders in the Decision-Making

Figure 2 provides an overview of different stakeholders and their objectives, aiming to understand inefficiencies in hospitals, improve resource utilization, or to maximize profit.
We embed multiple mathematical models and its solution approaches from the literature to support these objectives in an integrated decision-making environment. End users such as hospital administrators, healthcare analytics specialists and other decision makers can use the proposed workbench to demonstrate/explore how mathematical models can improve resource planning and allocation decisions in hospitals. Furthermore, we illustrate the use of the workbench in a Continuous Improvement Unit (CIU) of a health board, described as a case study later in this paper.

Finally, Cayirli et al. [10] develop an appointment scheduling model that is also located on the operational decision level. It is implemented in an open-source online decision support tool and therefore not limited to a specific operating system.

We note that the systems which were published in the literature so far only support one of the three hierarchical decision-making levels, focusing either on the strategic, tactical or operational level. None of these applications integrate all three levels in one decision support tool. This ability will eventually allow opportunities to link solutions across the interfaces of these levels. To summarize, the main innovations of our E-HOSPITAL platform are two-fold: i) A unified, flexible and extensible workbench that combines different mathematical models of hospital resource planning problems by combining three classical hierarchical decision-making levels; ii) Formal, algebraic specifications of extensions of existing mathematical models are provided, implemented, and can be solved to optimality using sample instances, thus combining IT, operations and healthcare analytics in a single platform.

The remainder of this paper is structured as follows. We describe the workbench implementation and how we consider features that are highly relevant for practice by illustrating the use of the tool. Following this, we demonstrate the application of the workbench in a case study based on demand and capacity planning for hip fracture patients using real-world data from two hospitals. Lastly, we conclude with ideas for future work to extend the workbench, specifically highlighting opportunities linking the multiple levels.

### Methods
When implementing the workbench, we focused on widely acknowledged theoretical concepts from the decision sciences literature that break down planning problems into different decision levels. When developing our modelling extensions, we incorporated practitioner’s feedback into the existing models.

### Implementation of the Different Decision Levels
Using the design objective of [2], seven approaches were selected from the literature that apply mathematical programming methods to provide decision support for healthcare OM problems. We also took into account the planning matrix of Hans et al. [19] who provided a similar classification of problems on the strategic, tactical and operational decision-making levels.

### Strategic Decision Level
The strategic planning involves decision processes related to allocating resources, controlling organizational performance, establishing broad policies, and evaluating capital investment or merger proposals [26]. Decision support tools at this level need to help decision makers envision the future and negotiate with stakeholders by examining multiple scenarios [26].

These analyses are exactly what our workbench is aiming to provide: On the strategic level, Busse et al. [8] and Blake et al. [6] were selected. Both papers decide on the case mix of patients in hospitals while capacity constraints are considered. The difference between the two models is that Blake et al. [6] had target levels of physicians for treating patients and target revenue of the hospital, among others. In contrast, Busse et al.[8] followed an aggregate planning level to decide how many cases a hospital can support, given constrained resources. As a consequence, analyses can be run such as: Given operating room and bed capacity, what is the feasible number of patients to be treated within hospital budget limits?
Another scenario analysis is to examine the impact on revenue and the number of patients to be treated, given an increase or decrease in capacity.

**Tactical Decision Level**

Our workbench’s tactical decision level consists of the tactical admission problem devised by Hans et al. [27]. Moreover, we include Master Surgical Scheduling (MSS) problems into that decision level, selecting the approaches of Blake et al. [7] and [25]. The difference between the two MSS papers is that Van Oostrom et al. [25] incorporate uncertainty into the planning while the approach in Blake et al. [7] is entirely deterministic.

**Operational Decision Level**

On the operational decision level, the operational shift scheduling problem in Beaulieau et al. [4], as well as an extension of the hospital-wide patient flow problem in Gartner et al. [14], were implemented.

**Model Extensions**

Before implementing the different models, we extended them to improve their applicability. On the strategic level, we extended the work of Busse et al. [8] on a temporal dimension. This allows users to insert expected values for different time periods for demand broken down by different diagnosis-related groups (DRGs). Another extension was the tactical planning problem of Vissers et al. [27] in order to capture demand for physical therapists and therapy rooms in the admission planning of patients. On the operational planning level, we extended the model of Gartner et al. [14] in order to capture admission decisions of patients, among others. The extensions are described in more detail on the workbench’s repository: [https://github.com/drdanielgartner/ehospital](https://github.com/drdanielgartner/ehospital).

**An Illustration of the Workbench**

Figure 3 provides a specific example of the digital workbench. As can be seen, it separates the strategic, tactical and operational decision level using three tabs that are arranged vertically in the graphical user interface (GUI). Then, in each of the different planning levels, tabs are arranged horizontally, which separate the different approaches from each other.

The illustration selects and solves the case mix planning problem of Blake et al. [6]. The GUI shows pre-specified default values e.g. for the number of case mix groups desired for each physician or the hospital capacity (e.g. beds and operating room time). After solving the problem instance, the user can store the output in a text file, which provides information about the generated solution which also includes the objective function value and the cases assigned to each physician.

**Installation Requirements**

Before running the jar file of the platform-independent environment which, again, can be downloaded at [https://github.com/drdanielgartner/ehospital](https://github.com/drdanielgartner/ehospital), IBM ILOG CPLEX [20] has to be installed. Also, at least version 6 of the Java Runtime Environment has to be installed.

**Results**

In this section, we describe how we incorporated a capacity planning model into the platform and how we carried out an analysis for a real-world project with a health board in the U.K.

**Incorporating Capacity Planning into E-HOSPITAL – A Case Study**

The objective of the case study is to show how the E-HOSPITAL workbench can be extended and used to support a real-world decision-making scenario. The task is to determine the optimal level of operating room and bed resource capacity required for treating hip fracture patients in a multi-hospital site in the United Kingdom. This problem is located at the strategic planning level. Rather than deciding on a narrow scope i.e. on individual patients at the operational level (e.g. patient scheduling decisions [18]), we decided on a broader scope, which is less structured and constrained [6]. Additionally, Busse et al. [8] models seem at first glance to be highly suitable. However, the board of directors who will use the decision support tool in future needs to determine the resource capacity level rather than the optimal number of patients given fixed capacities. Also, the board had specific usability requests e.g. to vary patient demand and length of stay.

**Research Questions**

The research questions which can be broken down into analytics and services planning are as follows:

**Analytics-focused research questions**

- How many patients require the service during a one-year planning horizon?
- What is the length of stay distribution of patients requiring hip fracture treatment in each of the hospital’s catchment areas?

**Strategic planning questions**

- Fixing the catchment areas to the hospital sites, what are the total amounts of operating room time and bed capacity required?
- Pooling hospitals, what are the resource requirements for each of the hospitals?

Figure 4 – Hip Fracture Demand and Capacity Planning

When carrying out the case study, we broke this project down into different phases as shown in Figure 4. In what follows, we will provide more details for each of the different project phases.

Transparency

In the first phase of the project which we called the “Transparency Phase”, we evaluated the length of stay (LOS) distribution because, in healthcare delivery, this is a major source of uncertainty and costs. Our data analysis revealed that the two hospitals that we studied (henceforth denoted as hospital 1 and hospital 2) are faced with a large inter-quartile range of LOS. Moreover, the median LOS is 28 days for hospital 1 and 23 days for hospital 2.

A more detailed analysis of the LOS data using histograms and Gaussian Kernel Density Estimators (KDEs) is shown in Figure 5. It reveals a left-skewed shape of the LOS distribution, which is similar to LOS distributions that can be observed in previous research [17, 23].

Mathematical Modelling

In the mathematical modelling phase, we used a model which is available in the workbench’s github repository. The model was developed in collaboration with Orthopaedic physicians and the GUI in collaboration with the physicians and the Modelling Lead of the Aneurin Bevan Continuous Improvement Unit (ABCi). The result is shown in Figure 6.

The upper part of the workbench revealed that patient demand reached 271 and 278 patients in the catchment area of hospitals 1 and 2, respectively, with the median LOS at 28 and 23 days. Manipulating the slider below the “#Patients” label and the slider below the “LOS quantile”, we observe that, for example, we can run our analysis for up to 50% more patients as compared to the baseline demand. Also, we can select any quantile for the LOS distribution. This reflects risk sensitivity for practitioners while ensuring that enough bed and operating room capacity is determined by the mathematical model since demand is fluctuating.

Assumptions, Analyses & Recommendations

For our analyses, we assumed that the average duration of a hip fracture surgery is 2.5 hours. To determine the demand, we selected patients admitted to the Accident and Emergency Unit (A&E) in 2014 and patients who were discharged from the hospital in 2014. We set up two scenarios as follows: Scenario 1 consisted of a run where we used the median (50% quintile) for length of stay. Also, we focused on actual patient demand observed in 2014. Moreover, we ran the model with a fixed assignment of patients to hospitals. This means that patients who arrive from hospital 1’s catchment area are exclusively treated in that hospital. The same holds true for hospital 2. In the second scenario, we include a third hospital (hospital 3) which will be built in the near future within the health board. In this scenario, the objective is to level bed capacity.

The results of the scenario analysis revealed that using the fixed model, approximately 7,588 and 6,394 bed days are required for hospital 1 and 2, respectively. The results using the flexible model for three hospital sites (Figure 6) revealed that 4,661 bed days are required for each of the hospital sites. However, one can observe that the operating room capacity is different across the hospital sites which is attributed to the different patients’ LOS. Fewer patients are admitted to hospital 1, but have the same total bed days due to their longer LOS, but lower total OR capacity requirement.

Discussion

Compared with the current state of the art, the proposed platform can be considered as the first that unifies multiple models in one platform and extends it to increase the acceptability in health care. Another contribution that extends current state of the art is that multiple decision levels can be tackled by using this platform. One limitation, however, is that the commercial solver CPLEX has to be installed with the platform.

In the scenario analysis that we provided in the results section, we employed realized patient demand as a predictor for future demand. In other inpatient settings and especially for elective patients, the size of waiting lists has to be accounted for as well. Also, there are many more factors that determine length of stay such as quality of care, hospital discharge policies, and so on. However, many of these can be incorporated as site-
specific parameters into the mathematical models and solved for varying scenarios of parameter values.

**Conclusion**

In this paper, we described the development of a unified digital workbench for hospital resource planning that is based on a well-accepted, multi-level decision-making framework. The platform leverages information technology, operations management, and data analytics to support not only healthcare decision makers but also healthcare analytics and information systems specialists as well as educators of these topics. The tool combines the three classical hierarchical decision-making levels in one integrated environment. At each level, several decision problems can be chosen. Extensions of mathematical models from the literature are presented and incorporated into the workbench. In a case study using real-world data, we demonstrated how we used the workbench to inform capacity decisions in a multi-hospital site.

Future work will address the intersection between the different decision layers. Although the intersection between the strategic and the tactical layer have not yet been covered extensively due to computational complexity, our aim is to provide computationally tractable, heuristic methods to evaluate the intersection between multiple decision layers when optimal approaches are not feasible.

Abstract

This paper uses consumer health informatics as a framework to explore whether and how direct-to-consumer personal genomic testing can be regarded as a form of information which assists consumers to manage their health. It presents findings from qualitative content analysis of web sites that offer testing services, and of transcripts from focus groups conducted as part a study of the Australian public’s expectations of personal genomics. Content analysis showed that service offerings have some features of consumer health information but lack consistency. Focus group participants were mostly unfamiliar with the specifics of test reports and related information services. Some of their ideas about aids to knowledge were in line with the benefits described on provider web sites, but some expectations were inflated. People were ambivalent about whether these services would address consumers’ health needs, interests and contexts and whether they would support consumers’ health self-management decisions and outcomes. There is scope for consumer health informatics approaches to refine the usage and the utility of direct-to-consumer personal genomic testing. Further research may focus on how uptake is affected by consumers’ health literacy or by services’ engagement with consumers about what they really want.

Access to Information; Consumer Health Information; Genomics

Introduction

Advances in healthcare have created a need for informed consumers. To meet this need, the Internet has provided a way for consumers to access information; including access to medical literature, connection with patient social networks and the creation of open health data. Notoriously, the Internet is also a massive source of misinformation about health. Consumer health informatics (CHI) is concerned with the health information structures and processes that enable people who are not clinically trained (so-called “consumers”) to be informed for the purpose of managing their own health. Some consumer health information resources are purpose-built, such as health information literacy aids and personal health records, while others show technological appropriation, for instance using Facebook, Youtube or Twitter for health self-management.

From a synthesis of findings reported in recent reviews [1, 2], the focus of CHI is on the types of tools or methods that can make valid health data, information and/or knowledge resources available to consumers, and the aim of CHI is to understand and improve the ways that these tools or methods: enable access, materially and intellectually, by consumers; address the health needs, interests and contexts of consumers; allow direct interaction by consumers without the presence of a healthcare professional; personalise and / or socialise consumers’ interactions about their health needs and interests; aid consumers’ health self-management and/or self-reported outcomes; facilitate consumers’ engagement in clinical diagnosis and/or treatment. This paper uses these CHI considerations to explore one relatively new health-related phenomenon on the Internet.

Health-related personal genomic testing services have been available directly to consumers over the Internet for about ten years. Consumers register with a service, create a user account and make a payment online, then use a postal or courier service to ship some saliva or other body tissue to a laboratory, and generally receive their test results and interpretive information by email. These services are increasing in number and reach [3]. Currently over 130 service providers advertise to consumers in the English language; many of them do not require a clinical referral and are priced cheaply by comparison with clinically mediated testing [4]. Popular uptake is rising. One service, Mapmygenome (www.mapmygenome.in), according to its publicity materials, aims to touch 10 million lives and save a million lives by 2030.

However, there are mixed views as to the benefits and risks of direct-to-consumer personal genomic testing (DTC-PGT) – for example, whether empowerment or overdiagnosis is more likely to be its net result [5]. In Australia the direct sale by company of a direct-to-consumer personal genome test for health information is prohibited. However, many companies in Australia have adopted a model where they offer a personal genome test such that the sample is processed overseas. Further, Australian regulations do not stop consumers from arranging online for tests to be done outside their country of residence. Health authorities can only caution consumers about their use [6].

The function of DTC-PGT as a form of consumer health information is acknowledged by the US National Library of Medicine [7] and its use as such has been investigated in controlled settings [8]. An opportunity to use a CHI lens to form a clearer view of the information structures and processes that typify DTC-PGT using real-world data has arisen through research in a multi-disciplinary, multi-stage study to explore broadly Australians’ expectations of personalised genomics. The Genioz (Genomics: National Insights of Australians) project (www.genioz.net.au) which began in 2015 involves focus groups, a quantitative survey, semi-structured interviews and ethical critique.
This paper specifically reports research into DTC-PGT services available to Australian consumers, and into public ideas about these services that have emerged in Genioz focus groups. Our aim here is to use CHI as a framework to explore whether and how DTC-PGT can be regarded as a form of information which assists consumers to manage their health.

Methods

We used two data sources. First within the broad definition of DTC-PGT provided to consumers by the US National Library of Medicine [7], we selected web sites to represent a cross-section of services offering wellbeing, disease, individual and ancestral information, including some market leaders and some less well known companies. We analysed web site content that was publicly accessible in late 2015 from 10 different providers, on a total of 69 web pages: AncestrybyDNA, DNA Worldwide, EasyDNA, FamilyTreeDNA, GenetrackAustralia, GenomicsforLife, GTLDNA, Mapmygenome, PathwayGenomics, 23andMe. Data from web sites is not identified by company name, so as to avoid potential perception of bias.

Then we analysed the transcripts of seven age-category stratified GeniOz focus groups in two capital cities in 2015, involving a total of 56 members of the public. People were recruited regardless of whether they had ever undergone personal genomic testing; purposive sampling was done for gender and age. Apart from individuals’ gender and age details, data are de-identified to protect confidentiality.

Since these datasets were not generated specifically to explore consumer health informatics aspects of DTC-PGT, we took a summative approach to analysis, that is, identifying certain content with the purpose of understanding it in a particular context [9]. We used a coding guide (Table 1) to identify content, a framework method [10] to chart its occurrence, and an abstract level of interpretation [11].

The coding guide supported a junior researcher to perform a systematic search for terms associated with managing data, information, and/or knowledge (manifest content); these three fundamental information science concepts align with formal models of health informatics [12, 13] but are often used interchangeably in everyday language. Then the latent content of the charted occurrences was analysed by a senior researcher with consumer health informatics expertise, in the context of the CHI concepts and concerns summarised in the Introduction section of this paper.

This study is preliminary to a more in-depth analysis of a larger dataset from the GeniOz project. In a larger-scale and more nuanced study, quantification of manifest content will have greater significance and other Smethods, such as sentiment analysis, also may be illuminating.

For the purpose of the present exploratory study the Results section of this paper provides selected examples only of manifest content analysis, and the Discussion singles out noteworthy results of latent content analysis.

Results

Resources and Services Offered by DTC-PGT Providers

Data is the primary resource offered to consumers of PGT services, in the form of reports of results from tissue sample testing. These reports may cover a wide spectrum of aspects of health, wellbeing, fitness and identity, based on a variety of markers, accompanied or not by raw data files. A summary of what is offered on the ten provider web sites (represented by numbers 1 to 10) is as follows:

1. Genetic information categorized four ways: carrier status, wellness, traits and ancestry. Over 100 health conditions and traits. Provides raw data.
2. Paternity, relationship, prenatal, ancestry, clinical, other tests (genetic fingerprinting, DNA profiling), health tests (skin, children’s DNA, diet, nutrition, fitness, wellness, weight and lifestyle), animal tests. Based on 21 markers. Provides raw data.
3. 50 physiological and lifestyle traits, health conditions and inherited conditions. Personal, brain wellness, TB diagnostics, molecular diagnostics, forensics, merchandise. 16 markers. Provides raw data.
5. General health and wellness, liquid biopsy, hereditary cancer, pharmacogenomics, carrier screening. A variety of conditions including cancer risk, cardiac health, inherited diseases, nutrition and exercise response, as well as drug response for specific medications including those used in pain management and mental health. 75 markers. Provides raw data.
6. DNA origin, DNA world view, paternal and maternal. Raw data available is limited. 144 markers.
7. Disease screening, prenatal screening, paternity, immigration, > 700 inherited diseases.
8. Family finder, father’s line (37, 67 or 111 markers), mother’s line. Raw data provided in CSV or XML format.
10. Paternity, prenatal, relationship, ancestry, other tests (infidelity DNA testing, DNA profile, surrogacy DNA testing, additional services, semen detection DNA testing service, genetic reconstruction testing, non-invasive prenatal test for Down syndrome). 21 markers.

Some data management features are explicit on some web sites, such as these examples of access, security, and visualization:

“choose to authorise [the provider] to share their data with specific individuals” (1)
“access an interactive version of your report anytime, anywhere” (5)
“once the testing is completed and the results provided to the client, all raw data is purged from our system” (6)
“browser allows you to see where on your chromosomes a match shares DNA with you” (8)

Information services that contextualise results reporting may be available. Selected examples are:

“reports in four categories: carrier, ancestry, wellness and traits” (1)
“interesting facts about your own haplogroup…. access to information about your extended genetic cousins” (2)
“an expert review of your case looking at possible reasons for the results” (4)
“a detailed manual that explains your results” (6)
“an in-depth guide to understanding and interpreting your results” (8)

Information filtering also appears, in the form of messages advising on appropriate use of the data. For example, seven providers’ web sites included content that recommended against using their genetic tests for clinical or diagnostic purposes. Some providers socialise the sharing of information by hosting user comments. For example:

“very interesting, but I'm a little unhappy that the information provided for conditions genetic genealogy and inter-species genealogy is so poor despite a fantastic database, genbank and published tables for much of this stuff” (1, user comment)

Knowledge management facilitation for users is promoted prominently. Providers’ web site content uses the language of insight into self and others, actionable information, decision-support. For example:

“knowing your level of genetic predisposition toward developing particular conditions can help both you and your children live healthier and longer lives” (2)

“help you understand what your genetic variations mean and how it may affect you. … learn about inherited and acquired genetic health risks” (3)

“reports provide actionable information and recommendations that provide individuals with a roadmap to achieve optimal heart health” (5)

“discover your geogenetic links by seeing your match with studied populations and anthropological groups around the world” (10)

Several providers offer access to online genetic counselling or other clinical services, as a way for consumers to leverage test results and information. Knowledge management may also include suggestions on engaging expertise, for example:

“empowers the physician to help patients make informed decisions regarding diet and exercise, while also providing information about medication response” (5)

Communicating with other service users or other communities of interest is sometimes an option, for example:

“enhance your experience with relatives” (1)

“names and emails of your matches … are provided to you in order to collaborate” (8).

Ideas about DTC-PGT Held by Members of the Public

Examples of considerations that members of the public (Participant ID number / Gender / Age) voiced about managing data, information and knowledge are provided here. Key data management concepts were access and governance. For example:

- The right to data (restricting citizens’ access to information was the way one person interpreted one DTC-PGT provider’s legal issue over non-compliance with laboratory testing regulations):
  “the authority in the [United] States said ‘no you can’t do that’, they didn’t feel it appropriate that people should know this information because they may misunderstand it which is rather strange, there is a big battle going on at the moment and it looks like they are going to get the okay to release that information” (P40/M/72)

- Direct and timely access to the data:
  “go online and find this stuff and just put an order in, pay for it and get it delivered to our door” (P5-6/F/36)
  “you get massive bottlenecks … now you’ve got the thousand dollar human genome and the twenty dollar bacterial genome … why they don’t just sequence things in the hospital more often” (P23/M/22)

- Management and governance of the data:
  “I’m only interested in looking at myself, I don’t like it to be publicly accessible or set up as a database” (P12/M/32)
  “they [test providers] might keep a database of all the genetic information about you, for future reference” (P13/F/25)
  “the legitimacy of the company that is handling it, what might they do with it” (P14/F/20)
  “who are you going to offer these tests, how are you going to dictate what information is given out on the test, how are you going to ensure the validity of these tests” (P23/M/22)

People expressed attitudes about information management issues, particularly usefulness and shared use:

- Information usefulness limited in scope:
  “this genetic testing gives you a window into what the possibilities are, but it doesn’t define you” (P20/M/23)
  “if I paid my hundred dollars today I don’t know that it’s actually better than what it might be if I survive another ten years, if I’m getting imperfect information how useful is the information” (P23/M/22)

- Information usefulness contingent on external validation:
  “find other people who have done the test … a while ago and then see if the things that came back from their test … what good are they, the test[s], a certain number of years down the track” (P7-6/M/22)
  “if the website looked really legit … if the government was recommending it … if other people say this genetic testing has really helped me … it depends on the person delivering the message and how they interpret it for you” (P25/M/21)

- Information usefulness linked to clinical consultation:
  “if having an understanding of genetic make-up is providing information that shows patterns in or information about it will help health conditions and that can then inform medical practitioners to come up with preventative measures” (P5-1/M/41)
  “if my doctor said I would gain a lot from this I would do it” (P25/M/21)

- Information uses shared with other parties, not necessarily aligned with the consumer’s values:
  “people who want to try and genetically dictate what their children’s genes are going to be” (P14/F/20)
  “that information would be really useful for me … but for my health insurer, that’s an extra risk for them” (P53/M/42)

Knowledge management attitudes of members of the public were mixed.

- Self-knowledge for its own sake, sometimes with unrealistic expectations:
  “sometimes just knowing can make things a lot easier and having more time to understand it and understand what’s going to happen and … knowing a timeline, it’s almost like knowing this is what I have before this is going to start setting in” (P7-1/F/24)
  “for a company to say, we can decode it and tell you with any certainty … psychologically, it could be wish fulfilling” (P6-2/F/63)
  “if I did find out that I’m going to have an issue with my health in the future, I wouldn’t want them to tell me when it was going to be, I wouldn’t want to put a timer on myself” (P7-6/M/22)
Knowledge for the sake of significant others:
“for the benefit of my next generation, yeah, and I can afford it, I will definitely go for that. To find out if there’s anything which can be mended before [conception / birth]” (P5-4/F/45)

“whilst I don’t want my information, I really don’t want to know where my life’s going to go to, I sort of feel that for my child or a grandchild or another person, I would do that and find out because it’s something that can be prevented” (P46/F/63)

“We’ve got a social responsibility … to find out whether we’ve got [conditions that could be passed on to children]” (P47/F/75)

Knowledge as a prompt to action; or a deterrent:
“if I knew I had a predisposition to melanoma, I wouldn’t be going out in the sun. It would change how I do stuff in my life, some genetic testing could change your behaviour” (P24/F/23)

“I considered whether or not I got tested to see if my body type was one that would gain muscle quicker than someone else … I considered it but then … if I did find out that ultimately I’m a really fat body … I’d give up on life … like ‘well there’s no point’ … and then … the course of your life changes” (P25/M/21)

“if you knew there was a tendency to diabetes in your inherited characteristics you might pay a bit more attention to your diet as you age” (P28/F/72)

Managing uncertainty or bad news:
“if you think you could get a report that you could get breast cancer, then you spend the next x number of years with sleepless nights thinking ‘oh am I going to get breast cancer or not, is today the day?’ … that sort of uncertainty is a little bit of a drawback” (P20/M/23)

“anybody can get their genome sequenced for a thousand dollars, and it means nothing … we have no idea what the mutations mean, we have nothing to compare them to overall, we have no baseline and no comparator, so that’s cool, you may have really good genetics, you may not” (P23/M/22)

“What that might allow me to learn about myself that I might or might not like … you’d measure your own genome with a view to find out something as I say that you might or might not like” (P58/M/57)

**Discussion**

Within the overall focus group dataset, comments that could be related to management of DTC-PGT data, information and knowledge occurred infrequently. This is not so surprising since the general aim of the data collection was to explore broader public attitudes and understandings regarding personal genomics. The variety of ideas that was put forward suggests that there is scope for more specific investigation on this topic.

People appeared to be unfamiliar with the specifics of DTC-PGT data reports and additional information services. Major concerns about privacy did not emerge from these groups. People had more to say about the aids to knowledge that they thought DTC-PGT could provide, and some of what they said was similar to the benefits described on provider web sites. Some expectations were inflated, for example, the idea that you can learn how long your life will be (though indeed some companies suggest that this is possible).

Turning to the broader question of how DTC-PGT can function as consumer health information, the findings here provide evidence that it has some of the features that would be advocated by CHI, and that it offers some scope for the kinds of improvements that could be guided by CHI.

In terms of features, its essential rationale is to allow consumers direct interaction with data, without the presence of a healthcare professional. It appears to enable access by consumers, both materially (people did not foreground connectivity or cost or other issues of accessibility) and intellectually, considering the information services that providers offer to explain testing and support reading of test results. Personal genomic test results by their very nature personalise consumers’ interactions with information about health, to the extent that they identify the individual’s inherited conditions, risk factors and potential response to therapies. Likewise, the fundamental connection between the individual’s test results and their genetic family members’ past, present and future socialises this form of consumer health information; further, some providers offer suggestions and facilities for a consumer to exchange data and information with family members and other consumers. A few DTC-PGT providers also encourage and support consumers to share data with a health professional, such as a genetic counsellor available through the provider, or their own treating clinician.

In terms of improvements, the validity of the data and the value of the surrounding service which DTC-PGT provides to consumers is a key unresolved aspect of whether it is fit for purpose as consumer health information. This is unresolved partly because the consumer’s personal genomic data is being reported and interpreted to them as a formulaic business transaction, within a dynamic field of knowledge where there is much still to be determined about the underlying biomedical science and social science. CHI could be applied to improve tools that assist with health literacy in this area and thus create more discernment in the consumer market for DTC-PGT and the after-market for medical services (as described in [14]).

This is unresolved also because web site analysis shows considerable variation in the description of services, so that it is complicated for consumers to make choices about whether a service provider will meet their health needs and difficult for them to be confident about using the ensuing information as a basis for health decisions. Within a model of self-regulation of direct-to-consumer services, there is scope for CHI to contribute to formulating and monitoring industry standards (on data management, for example [15]) and to developing aids that allow consumers to compare the services on offer.

On the question of whether DTC-PGT is actually working as a form of consumer health information, findings from the focus groups suggest that it has not yet captured widespread public attention, certainly in Australia. By comparison, other more conventional forms of consumer health information provided by public agencies (such as Better Health Channel) and private interests (e.g. BUPA Health and Wellness) are much more familiar to the Australian public. It is noteworthy that DTC-PGT has not taken off given high rates of Internet use (around 80% of Australians were using the Internet to look for health information nearly a decade ago [16] and 61% had purchased goods and services online during a three-month period surveyed in 2014-15 [17]).

This suggests that DTC-PGT as a model of consumer health information on the Internet may not be working in terms of the way it addresses two particular CHI concerns. Does it address the health needs and interests and contexts of consumers? People had no direct experience of working with DTC-PGT information to report. They had ambivalent ideas about whether it could do this – some expressed personal curiosity or a sense
of obligation to family members, but others said that they preferred not to know or that they wanted more assurance about the information quality. Does it help consumers with their health self-management decisions and outcomes? Some people hypothesized that it would be an effective tool to support healthy behaviours and constructive health actions including seeking professional help. Others were less certain, alluding to anxiety and unhappiness that could ensue.

What consumer health information works and why is often explained by consumers’ health literacy, or by service providers’ engagement with consumers about what they really want [18]. Both of these factors in DTC-PGT, and possibly others that were not identified in this study, deserve further research.

Conclusion

This paper presents an exploratory investigation of whether we can regard DTC-PGT as a form of consumer health information, in actuality or potentially. In actuality, it does not seem as widespread or well-known among the Australian public as one might expect from industry reports. Its potential as consumer health information is unclear overall. We found inconsistent offerings and divergent attitudes, and this situation is echoed in other places. On one hand a highly articulate consumer feels “seduced by the idea that it [information from PGT] fills a void in unanswerable questions, yet without enough knowledge to properly interpret its true ramifications” [19]. On the other hand a highly regarded physician argues that health and consumer authorities should put greater effort into working with reputable consumer genomics companies to allow them to deliver more health information [20].

DTC-PGT is an Internet phenomenon which has been the subject of considerable research, but perhaps not enough through the lens of consumer health informatics. Based on the exploratory study reported here, the question of whether DTC-PGT can be or should be taken seriously as a form of consumer health information cannot be resolved. However, the need to address this issue spiked sharply from April 2017 when, after years of deliberation, the US Food and Drug Administration finally made it legal for one DTC-PGT company (23andMe) to market genetic health risk tests for a limited number of conditions [21]. Whether and how the forms and functions of health information of this kind can be systematically made safe, effective, accessible and equitable will have a major influence on the DTC-PGT industry and on healthcare generally.

From a CHI perspective, that is, seeking to understand how the Internet may be used optimally to increase the reach and sophistication of high quality information, DTC-PGT surely warrants further research and development before its growing range of information products and services can be either dismissed or endorsed as aids to health self-management.

Designing a Mobile Health Application Prototype for the Management of Interstitial Cystitis/Painful Bladder Syndrome

Janessa Griffith

Abstract

The design of an early mobile health application (app) prototype to manage interstitial cystitis/painful bladder syndrome, a chronic condition characterized by recurrent pain/discomfort in the bladder, is described. The purpose of this app prototype is to help people who have IC/PBS manage and learn what triggers their symptoms. The researchers aim for this research was to provide an example of how sex and gender could be included into the design of a health information system. Based on a literature search of common symptoms and challenges faced by people living with IC/PBS, the researcher created an app prototype design including many features: resources for relaxation, mental health, intimacy, pregnancy, and daily life; reminders for appointments, and medication; logs for diet, activity, sleep, pain, menstruation; and a link to a public washroom location. This prototype will later undergo usability and content evaluation.

Telemedicine; Interstitial Cystitis; Medical Informatics

Introduction

Interstitial cystitis/painful bladder syndrome (IC/PBS) is a chronic condition and those who have it experience recurrent pain or discomfort in the bladder and pelvic floor in the absence of an infection/disease. Pain/discomfort, urgent and frequent need to urinate and nocturia are common symptoms of IC/PBS [1]. Some people experience worsened symptoms with particular foods, activities, and menstruation [1]. The disease is more prevalent in the female population, with approximately 3 to 8 million (2.7% to 6.53%) female adults over 18 years of age [2] and 2 to almost 5 million male adults (1.9% to 4.2%) between 39 and 74 years of age [3] in the USA experiencing IC/PBS symptoms.

Despite the prevalence, no app is available to manage IC/PBS symptoms. The goal of this research is to design an app prototype for IC/PBS management and to help those with IC/PBS learn what triggers their symptoms.

Another goal of this research was to demonstrate how sex and gender considerations could be incorporated into health informatics solutions to support inclusivity. For example, as people with IC/PBS who are female experience worsened symptoms during menstruation, considerations will be built into the prototype. Another study focusing on people with IC/PBS who are female found that participants voided more than 30 times per day during a flare, impacting all areas of their lives [4]. A flare refers to a period of increased or worsening of symptoms [5]. This may impact genders in different ways. For example, activities and responsibilities of people with IC/PBS may differ by gender (e.g. caregiving or social activities), and this app prototype seeks to consider these needs through its features.

Methods

The researcher surveyed the Canadian sites of the two most popular digital media stores for iOS and Android using the search terms “Interstitial Cystitis,” “painful bladder syndrome” and “IC/PBS.” No apps were available to manage IC/PBS. Only one app was available for people living with IC/PBS to monitor and make decisions about their diet and one app providing information. Based on a literature review on symptoms associated with IC/PBS [1–4, 6, 8–12], the researcher developed features for an app to help people with IC/PBS manage their chronic condition and learn to recognize what may trigger a flare. Specifically, the researcher identified common symptoms and patient concerns associated with IC/PBS and designed features aimed to help people manage this chronic condition. The researcher also identified ways in which the experiences of living with IC/PBS differed by sex and gender and tried to design features that would make the app more inclusive to these unique needs. Physicians and patients were not consulted for this preliminary design; however, they will be included for future iterations.

This app prototype represents the preliminary design, whereby features were drafted based on findings from the literature. Future iterations will include a user-centred design. A user-centred design was not explicitly used in this preliminary iteration because the researcher was more concerned with identifying what was already known in the literature and also due to budgetary constraints.

Based on these features, the researcher created a prototype design using Proto.io, online prototyping software.

Results

- The following features were included in the app prototype design:

  Information: The app prototype includes links to evidence-based websites where patients can learn about IC/PBS. Information is also tailored according to the sex, gender, and age of the user. For example, a user who identifies as being male would be directed
to physiotherapists who specialize in the male pelvic floor.

- **Relaxation**: The American Urological Association developed guidelines for managing IC/PBS and suggested several treatments: relaxation/stress management, pain management, patient education, and behaviour modifications [3]. Thus, the app prototype includes links to relaxation techniques.

- **Food and beverage log**: Another feature is a calendar diary where users enter the food and beverages they consumed, which corresponds to the pain log. This information may be helpful for users to present to their physicians to draw correlations between, for example, particular foods and symptom flares, and to support the development of a pain management plan. A study surveying participants on foods that worsened IC/PBS symptoms found that citrus, tomatoes, certain spicy foods, artificial sweeteners, coffee, tea, and alcohol were common triggers [6]. An app already exists to help people with IC/PBS select food that will not trigger their symptoms [7]. Thus, this app prototype includes a link for users to refer to this existing app.

- **Activity log**: Similar to the food and beverage diary, an activity log is included (Figure 1) which documents any exercise the user participated in, and events at particular times. This is also linked to the pain log. Thus, users can present this information to their care provider to identify potential activity triggers.

- **Sleep log**: People living with IC/PBS may experience difficulty sleeping due to nocturia and other symptoms [8]. Therefore, a sleep log is included to capture any correlations between sleep disturbances, and, for example, diet, or physical activity.

- **Pain log**: People who have IC/PBS may experience pain in the form of burning during urination, or pressure/discomfort felt on the urinary tract/pelvic floor [9]. A log function is available to record when the user experiences pain, the type of pain (i.e. burning during urination, or pressure), and the severity.

- **Menstruation log**: The app prototype is also tailored according to the user. For example, if the user identifies as being female, features specific to menstruation symptom fluctuations will be present. Particularly, research suggests that symptoms may flare during perimenstruation [4]. Therefore, the calendar feature will also track menstruation cycles to potentially plan for pain management.

- **Report generator**: The app prototype includes a report generator (Figure 2) whereby values entered into the log functions (i.e. diet, activity, sleep, and menstruation logs) will be compared to the pain log. This function will help to potentially identify what triggers pain. For example, the user may notice that they have more pain during times when they have consumed orange juice. Users can then discuss these correlations with their physician in order to identify flare triggers. A disclaimer will be included, alerting the user to always discuss any potential patterns they find with their physician before making any lifestyle changes to ensure appropriate use of the app.

- **Medication reminders**: The app prototype also has a feature where users can enter the medications that they are taking, and an alert will remind them when to take their next dose.

- **Appointment reminder**: An appointment reminder function is present to alert users of upcoming appointments with their family physician, urologist, or other specialist. As well, people with IC/PBS may seek chiropractic, biofeedback, psychotherapy,
acupressure/acupuncture, and massage therapy to manage their symptoms [4], further warranting an appointment reminder function.

- **Mental health and social resources**: A study by Rabin et al. [4] found that people living with IC/PBS reported more depression than the general population [4]. These authors note that people with IC/PBS could benefit from psychotherapeutic intervention, to increase one’s sense of self-efficacy, and minimize self-stigmatization [4]. Research also notes how people living with IC/PBS may face challenges with respect to pursuing social, work, and recreational activities [4]. Thus, this app prototype includes a feature that provides resources for users to access, such as a list of professional counselors and physicians in one’s area who specialize in depression in people living with chronic diseases.

- **Intimacy resources**: A previous study found that 88% of female participants with IC/PBS experienced sexual dysfunction [10]. Similarly, male adults with IC/PBS can experience pain with intercourse [11]. Thus, information will be available on treatment options such as physiotherapy, and cognitive behavioural therapy.

- **Public washroom locator**: A public washroom locator is also incorporated which identifies facilities in the user’s vicinity (based on their current location), as urination frequency and urgency are common symptoms [2]. Many public washroom apps are already available; therefore, this app includes links to these resources.

- **Pregnancy**: People with IC/PBS who are pregnant may face challenges such as worsening of symptoms. As well, certain medications may be contraindicated in those who are pregnant [12]. Therefore, informational resources will be available to support users who are considering pregnancy or who are pregnant.

Based on available literature regarding the symptoms and challenges of living with IC/PBS, features were incorporated into an app prototype design for chronic disease management.

**Discussion**

As no other app is currently available for IC/PBS management, this work offers design features that may be helpful for those with the disease. Each feature was designed based on symptoms and challenges present in the available literature that people with IC/PBS face, demonstrating how research can be incorporated into the development of a health app.

This work represents the preliminary design of an app for IC/PBS. The researcher plans to undergo several iterations of evaluation, examining both the usability and content before developing the app further. The prototype will be of high fidelity, meaning that all functions (e.g. buttons, menus, input) will execute. Each possible screen will be evaluated using the Evidence-based Heuristics for eHealth Literacy and Usability [13]. The content will be evaluated by experts such as general practitioners and urologists. After several iterations of evaluation, representative users (i.e. people who have IC/PBS) will be asked to evaluate the app. Once the evaluation of the design is complete, the app will be ready to be developed in collaboration with professional developers.

Previous research has explored how social, political, and economic forces can influence the gendered construction of health information technology [14]. However, these researchers note a lack of examples of how to consider gender when developing health information technology [14]. Although this research will offer an example of making health information technology inclusive, it will also be challenging to navigate this space, in the absence of defined approaches.

Another challenge to designing this app will be to not perpetuate the discourse that the female body is risky and in need of surveillance [15]. The app is designed for users to manage their IC/PBS and learn what triggers their flares; however, many of the features described in this app are logs (i.e. diet, menstruation, activity, sleep, and pain logs). Perhaps this presentation is inappropriate, and another format should be considered. Further research is warranted to determine the best approach to IC/PBS management that does not reinforce oppression.

The search to find relevant apps was limited to English; therefore, it is possible that an IC/PBS management app exists that is available in other countries or in another language. Many general pain management apps are available, which people with the disease may be using. Similarly, people with IC/PBS may be using apps for individual symptoms such as medication reminders or a food/beverage diary.

**Conclusion**

Overall, this research outlines the design of an app that is inclusive to all users, based on known symptoms and challenges of living with IC/PBS. It contributes to the limited body of literature on incorporating sex and gender into health informatics research. Features of the app prototype include reminders, logs, and resources that could be helpful for people with IC/PBS to manage their condition and learn what triggers flares. The prototype will later undergo several iterations of evaluation for usability and content. Future work will involve developing this into a fully functioning app.

**Abstract**

Knowing the dynamics of one’s daily stress is essential to effective stress management in the context of smart and connected health. However, there lacks a practical and unobtrusive means to obtain real-time and longitudinal stress information. In this paper, we attempt to derive a convenient HRV-based (heart rate variability) biomarker named cHRV, which can be used to reliably reflect stress dynamics. cHRV’s key advantage lies in its low maintenance and high practicality. It can be efficiently calculated only using data from photoplethysmography (PPG) sensors, the mainstream heart rate sensor embedded in most of the consumer wearables like Apple Watch. Benefiting from the proliferation of wearables, cHRV is ideal for day-to-day stress monitoring. To evaluate its feasibility and performance, we have conducted 14 in-lab controlled experiments. The result shows that the proposed cHRV has strong correlation with the stress dynamics (r>0.95), therefore exhibits great potential for continuous stress assessment.

**Keywords:** Stress, Psychological; Biomarkers; Heart Rate

**Introduction**

Stress is a feeling of psychological and physical tension in reaction to a challenge or demand. We all have experienced stress from time to time, if not every day. In a nutshell, stress is hard-wired as an “alarm system.” When our brain perceives threat, it signals our body to release stress hormones to prepare for the “fight-or-flight” response. Once the stressor is gone, the alarm system is meant to be reset so that our body can recover to a normal and relaxed state. Unfortunately, in modern life, the nonstop and pervasive stressors tend to always keep us on high alert, which over time, could lead to a broad range of health problems ranging from headache, depression to heart diseases [1-3]. This is why stress management is especially important more than ever, and it’s needed everywhere, especially places with high concentration of stress such as workplace, classroom etc.

According to a national survey conducted by American Psychological Association in 2012 [4], Americans consistently report stress levels that exceed what they believe is healthy. Specifically, in 2012, approximately seven in ten Americans reported that they experienced physical or non-physical symptoms of stress, including irritability or anger, fatigue and changes in sleeping habits. What is more troubling is that the survey unveils the fact that people are struggling to manage their stress and tend to choose ineffective activities as their coping mechanism. For example, sixty-two percent of adults report that the activities they use to manage stress involve prolonged screen time, such as browsing the Internet, watching TV, playing video games and etc.

Despite the growing evidence of stress’s epidemic impact on health, there still lacks practical solutions that offer support and proper intervention that help people navigate through their daily stress. This is largely due to the fact that there isn’t a means to obtain people’s daily stress dynamics in an unobtrusive manner. Measuring the levels of stress hormones, such as cortisol, is considered to be the “gold standard” and is able to provide an objective measure of stress level. However, it involves sampling and testing the subject’s saliva or blood, which is invasive and time-consuming. Although providing accurate measurement, the result is only able to reflect only a snapshot rather than the dynamics of one’s stress. Therefore, methods involving hormone testing are ill-suited for stress management.

In this paper, we propose a convenient HRV-based biomarker, (cHRV), that can be calculated only using photoplethysmography (PPG) data available in most consumer wearables. Due to its low maintenance and high practicality, cHRV bears great potential to make automated and personalized stress management possible. Not relying on custom devices other than a smartwatch, the computation of cHRV is designed to be passive and transparent to users with no extra cost, enabling a seamless integration into users’ daily life. Moreover, cHRV offers a continuous and real-time stress signal, which is not only valuable at the individual level, but also powerful in generating insights about stress when examined at a higher level, for example, workplace, classroom and etc.

Specifically, in order to reliably reflect one’s stress dynamics, cHRV is calculated using a number of physiological features based on heart rate variability (HRV), which is a commonly used indicator of Autonomic Nervous System (ANS) activities [5]. Studies show people under mental stress demonstrate a decrease in HF (high frequency) of HRV compared to a control group. Moreover, a sizeable body of research has also been dedicated to studying the link between HRV measurement and level of stress. The results suggest that HRV is a strong discriminative feature for distinguishing between stress and non-stress [6-8]. The changes in HRV is linked to the occurrence of stressors and is linked to each other due to the fact that the cardiovascular system is mostly regulated by the ANS through sympathetic and parasympathetic activities, which are also responsible for controlling body’s reaction to subjective stressors. Therefore, HRV-based signals can offer insights into the activity of sympathetic and parasympathetic
pathways, which in turn can reflect physiological stress in certain contexts.

The contributions of this paper are as follows:

- We propose a method of extracting a HRV-based biomarker (cHRV) from PPG that is reflective of the stress dynamics. The method is convenient and practical, and has great potential to offer support and proper intervention that help people navigate through their daily stress.
- We present the preliminary evaluation results that suggest the proposed biomarker is highly correlated with the stress dynamics.

Methods

The data collection was conducted in a controlled, in-lab setting. The primary goal of the experiment was to investigate the feasibility and effectiveness of using cHRV to capture stress dynamics. Therefore, all the experiments shared a fixed structure (shown in Figure 1) which was pre-defined to isolate and control the stressor that causes the stress.

Controlled In-lab Experiment

Setting

The experiments were performed in either office rooms or reserved meeting rooms where only one or two researchers and one subject were present. Prior to the experiment, the researchers will assist the subject with putting on the devices for data collection, and make sure data is being recorded properly. The devices used for recording physiological data include: 1) a wrist-worn device with PPG sensor and electrodermal activity sensor (EDA), 2) an electrocardiogram (ECG) sensor and 3) a headset with a 4-lead electroencephalogram (EEG) sensor.

Procedure

As shown in Figure 1, the in-lab experiment consists of 3 sessions including Baseline, Stress Test and Recovery. Specifically, during the Baseline session, we play guided meditation for 20 minutes to relax the subject as much as possible, in an attempt to minimize the residual stress from other prior stressors, if there is any. Therefore, the collected physiological signs at the end of the Baseline session should reflect the subject’s baseline state (when not under stress).

In the Stress Test session, we conduct a standard stress-inducing test where the subject is requested to answer a verbally asked, non-trivial arithmetic question (e.g., 2010-37=?) every 10 seconds for about 6 mins [9-10]. This session consists of two such math tests with a 5-minute relax in between them to protect the subject from being under excessive stress. With the stress test, we exposed the subject to two types of typical daily stressors, which are 1) the stress as a result of being requested to solve non-trivial problems, and 2) the stress from having to finish tasks under time pressure.

In the Recovery session, we use the same relaxation technique as used in the Baseline session to help the subject recover from possible elevated stress. Data collected during this session will be used to investigate the recovery process from a stress buildup.

At the end of each session, we asked the subject to rate his or her current perceived stress level (PSL) on a scale from 0 to 10, with 0 being not stressed at all and 10 being extremely stressed.

Subjects

The subjects consist of 12 IBM employees, mostly composed of young adults with a few middle-aged subjects. Our study along with its data collection procedure is approved by the Institutional Review Board. All the subjects voluntarily agreed to contribute to the data collection and signed a consent form. Individuals will be excluded if they have significant health conditions or take medications that interfere with stress tasks including diagnosed cardiovascular conditions (e.g., arrhythmia, hypertension), neurological disorders (e.g., seizure disorder, stroke, transient ischemic attack), mental illness (e.g., depression, panic disorder) and cognitive or attention disorders (e.g., attention deficit/hyperactivity disorder).

Dataset

During the course of the experiment, we have collected a rich set of raw data from various sensors (shown in Table 1). For performance evaluation, we extracted cHRV along with three other signals commonly used as indicators of stress for comparison (shown in Figure 3).

Extracting cHRV from PPG Signal

PPG sensor has been widely embedded in most smartwatches and fitness trackers. Similar to pulse oximeter, PPG is a light-based technology to sense the rate of blood flow as controlled by the heart’s pumping action. As shown in Figure 2, A series of operations are involved in the process of extracting cHRV from consumer wearables with motion sensor and PPG sensor.
To calculate RR intervals from PPG signal, we first perform a 6-order Butterworth low-pass filter on the original PPG signal, with a cutoff frequency of 2 Hz. This filtering process is intended to filter out noise irrelevant to heart beats as much as possible. Then a peak detection operation will be conducted on the filtered PPG signal to identify peaks in the signal that represents heart beats. Lastly, the time intervals between successive identified peaks are extracted, resulting in a temporal sequence of RR intervals.

A sequence of outlier-free, beat-to-beat intervals is essential to accurate HRV calculation. In order to obtain normal and reliable RR intervals, commonly referred to as NN intervals, we filter out the outliers in RR intervals with a correction procedure consisting of three steps. First, as motion artifact is the major cause to corrupted PPG signal, we filter out the RR intervals based on their corresponding motion level, which is derived using acceleration data collected from the motion sensor. In the second step, a standard threshold-based method is used to filter out abnormal RR intervals based on its duration and also the difference in duration between consecutive RR intervals. Lastly, a distribution-based method is used to identify and remove outliers within a sliding window.

After the RR interval correction, the resulted sequence of the NN intervals will be used to extract cHRV. In clinical practice, no less than five minutes of NN intervals is required to calculate short-term HRV features, although recent research studies have suggested that shorter windows (e.g., 60 seconds) [11] may also be sufficient, especially for time-domain methods. In our case, a five minute sliding window of NN intervals are used to extract cHRV. To ensure the reliability of the feature extraction, a Data Quality Control component is responsible for identifying the window with a high percentage of discarded RR intervals, which is a major sign of poor data quality, mostly caused by excessive motion. Only data within windows, with acceptable data quality, are used to calculate HRV-based features. Features including the total power of HRV SDNN (standard deviation of normal to normal R-R intervals) and the high frequency power rMMSD (square root of the mean squared difference of successive N-N intervals) of HRV will be combined to calculate cHRV.

Other Stress Signals Extracted for Comparison

To gauge the performance of cHRV in reflecting stress dynamics, we extract three other signals that are commonly used as indicators of stress and compare them with cHRV for evaluation purpose. Data used to extract these signals were all collected in parallel with the data used to derive cHRV. These stress signals include:

- **Skin Conductance (EDA):** The increase in EDA (Electrodermal Activity) signal indicates increased sweat production, which is commonly associated with sympathetic arousal.
- **Power of high-beta band of the brain wave (EEG):** increased power is associated with high arousal (e.g., stress and alertness)
- **Heart Rate (HR):** Certain stressful situations could lead to increased heart rate.

In Figure 3 we plot the cHRV signal along with the EDA, EEG and HR signals over time using data collected from a typical in-lab experiment. In these experiments, the subject’s stress level has been successfully elevated by the Stress Test session and later relieved by the Recovery session, resulting in an increase of perceived stress level from 1 to 3 followed by a decline from 3 to 1. A key observation of this case is that the EDA and cHRV are the signals that most reflected the subject’s stress dynamics. Specifically, a noticeable decline can be observed in both signals during the Baseline and Recovery sessions, which are designed to reduce previous stress and induced stress, respectively. More importantly, the increase in stress during the Stress Test session is clearly reflected in both EDA and cHRV. Interestingly, the effect of the short five minute resting in the middle of the Stress Test session is also captured, resulting in a brief dip around the thirtieth minute in both EDA and cHRV signals.

Results

The primary goal of the evaluation is to examine the cHRV’s ability and effectiveness in reflecting the dynamics of stress. The basic idea is to examine the correlation between a signal and the stress dynamics during the experiment.

Perceived Stress Level

![Figure 3 – Stress signals extracted from a 3-session in-lab experiments (from top: EEG, EDA, HR and cHRV signals), along with self-reported stress level at the end of each session.](image)

For evaluation purposes, we use Perceived Stress Level (PSL) as the proxy of the stress dynamics. PSL is reported by the subject at the end of each session on a scale from 0 to 10. The structure of our in-lab experiment was designed to see if the experiment showed a result in an PSL increase during the Stress Test session, and a PSL reduction after the Recovery...
session. In Figure 4, the normalized PSLs collected from 14 experiments are plotted over three sessions. Note that only two subjects' PSL reports are inconsistent with the structure of the experiment. Interestingly, one subject (A) reported reduced PSL in the Stress Test session (blue line Figure 4), although, all four stress signals suggest otherwise (blue lines Figure 5). Therefore we speculate that subject (A) might have a misperception of his or her stress level. Another subject (B) reported constant stress reduction (yellow line Figure 4) during the experiment. This could be largely because the subject began the experiment with relatively high residual stress built up from work or other previous activities, rendering the stress-inducing session ineffective. Although the Stress Test did not work as intended, the cHRV successfully captured data that showed a constant stress reduction over the experiment (the yellow line shown in Figure 5d).

Correlation-based evaluation

To investigate and demonstrate cHRV’s effectiveness in reflecting stress dynamics, we calculate all four aforementioned stress signals’ correlation with the subjects’ perceived stress level for each of the experiments.

Specifically, we first conduct simple processing on the signal contained in each session, resulting in a sequence of three values for each signal. Due to inherent nature of the three sessions, the value is calculated by averaging the last five minutes of signals for Baseline and Recovery sessions, and the entire twenty minutes of signals for Stress Test session. Figure 5 shows the normalized result for each signal. Lines with the same color in Figure 4 and 5 represent data from the same experiment.

Next, for each experiment, we calculate Pearson Correlation between the corresponding stress signal shown in Figure 5 and the reported PSL shown in Figure 4. The result is plotted in Figure 6. We can see that cHRV achieves the highest average correlation (r>0.95) with the most reliable performance. In contrast, other signals such as EDA and EEG failed in reflecting the stress dynamics, resulting in lower correlation with PSL. As we can see in Figure 5a, although EDA signal is able to capture the stress dynamics in most of the experiments, there are several results where the elevated stress in the Stress Test session were incorrectly measured as reduced stress. This could be mainly because that the skin conductance is also affected by other environmental factors such as room temperature, therefore adding uncertain noises. In Figure 5b, we can see that the EEG signal is accurate in detecting the decline in stress level in Recovery session, but tends to yield unreliable measurement for Baseline session.

Discussion

In this experiment, we use perceived stress level as the proxy stress indicator because there lacks ground truth on exactly how stressed people are. However, we have learned from the subjects that there may exist a gap between one’s psychological perception of stress feeling and physiological measurement of stress response, as illustrated by Figure 4 that subject (A) might have a misperception of his or her stress level. To further probe this problem, we propose to categorize the perception-measurement levels into four groups, as shown below:

However, the current experiment is limited by the number and diversity of subjects. In the next phase of this study, we will recruit more subjects, then categorize them according to these four groups, and analyze for each group what characteristics are representative and what factors or context contribute to the misperception (Groups 1 and 4). This line of research work will help us establish unique user stress profiles and identify influencing stressors and contexts. The goal is to provide in time, continuous feedback to users so they have a better self understanding on how their minds and bodies function and respond to various stressors.
This is an essential step towards stress management. Our proposed cHRV method also offers a valuable objective addition to widely used psychological instruments for measuring self-reported perceived stress scales (PSS) [12] by providing real-time convenient physiological measures in daily life.

Another valuable insight gained from this experiment is that same physiological features could mean different stress indexes for different users, as shown in Figures 5 and 6. Therefore, one-size-fits-all detection model will not provide accurate and meaningful results for everyone. The proposed stress monitoring approach takes into account the individualized stress profile, which will be adjusted, using user’s sparse stress labeling (e.g., users’ perceived stress level at a certain time), so that it can gradually adapt to the user’s unique physiological response.

Driven by the proliferation of wearable devices, the authors believe the ability to continuously monitor and manage stress in real-time is a critical component of this new exciting commercial domain. Although future studies are needed, the initial results of cHRV from PPG sensors, the mainstream heart rate sensor embedded in most of the consumer wearables, has shown its potential to not only enable researchers to explore practical, continuous, unobtrusive and personalized stress management, but also empower users to stay aware of their stress level in real-time and effectively and efficiently manage their stress on a daily basis.

Conclusion

In this study, we experiment practical and unobtrusive means to obtain real-time and longitudinal information about stress. The proposed cHRV approach uses proliferated consumer wearables to derive a convenient HRV-based biomarker to reflect daily stress dynamics. We compare and evaluate the feasibility and performance of cHRV through in-lab controlled experiments with other biosensors, including EEG, EDA and HR. The result shows that the proposed cHRV has strong correlation with the stress dynamic, and therefore exhibits great potential for continuous daily stress assessment with reasonable reliability and high practicality.

Abstract

Significant efforts have been made to improve physician-to-physician communication and care coordination during transition of care in order to reduce adverse events and readmissions. As electronic health records (EHRs) become widely available, many hospitals have implemented physician collaboration and hand-off tools to automatically send admission notifications, discharge summaries, and pending laboratory results to a patient’s primary care physician (PCP). However, the effectiveness of such tools depends on a fundamental question that remains unstudied: who is the patient’s PCP? Missing or outdated PCP information may become the bottleneck to effective patient-centered care coordination regardless of existing efforts on promoting interoperability among healthcare providers. In this paper, we characterized patient-reported PCPs and experimented with an imputation algorithm that automatically infers a patient’s primary provider based on patient-provider encounter data. We compared the imputation results with patient-reported PCPs and suggested practical uses of our findings.

Keywords:
Physicians, Primary Care; Patient-reported; Care Coordination

Introduction

Primary care physicians (PCPs, also known as general practitioners) play a critical role in providing continuing care of patients, especially those with complex health needs [1]. PCPs coordinate care among various care team members of a patient by communicating with hospitals, emergency departments, specialty care, home care and social service providers. Studies have reported that increased involvement of PCPs is associated with lower readmission rates [5,6]. However, numerous studies have shown that timely outpatient follow-up is associated with lower readmission rates [5,6]. However, studies also reported that poor communication among physicians across care settings have posed practical challenges to coordinated care. In a study of primary care physicians across the industrialized world, only 31% of physicians surveyed said that they were always notified when a patient is discharged from the hospital and 32% for emergency department visits in the United States [7]. Similarly, communication between PCPs and specialists regarding referrals and consultations is often inadequate. A study reported that 80% of specialists said they “always” or “most of the time” send consultation results to the referring PCP, but only 62% of PCPs said they received such information [8].

To promote effective communication among physicians during transition of care, most previous studies focused on designing hand-off tools or evaluating the availability and content of discharge summaries [9,10]. As the adoption of EHRs among hospitals and individual practices increases, many EHRs are configured to automatically fax or electronically send discharge summaries to PCPs upon patient’s discharge. However, such automated services rely on accurate and complete PCP information captured in EHR or associated administrative systems. In other words, the practical value of the transition of care tools depends on the assumption that the hospital or specialist knows who the patient’s PCP is and where to send discharge summaries or consultation notes. In reality, the PCP is not reliably captured. Hospitals are often faced with the challenge of missing or outdated PCP information in their system. Discharge summaries may be sent to an invalid fax number or the wrong physician if the patient has changed PCP for various reasons. The inaccurate PCP information causes communication lapses and poses significant privacy concerns considering the protected health information (PHI) contained in the documents.

Research into the clinical implications of accurate patient-PCP relationships has deferred to the focus of measurement for the operational payment imperative. In the health insurer industry, in order to measure a provider’s performance, members (patients) are attributed to a provider through an analysis of healthcare claims [11]. Attribution rules vary across organizations, depending on the objectives and application. However, this patient attribution approach only focuses on insurance members and providers who participate in certain incentive programs such as the ACO delivery model or a specific health plan network. Our study examines the PCP relationship from a patient’s perspective and is targeted at the complete patient population, including those uninsured and underinsured.

In this study, we focused on answering some fundamental questions regarding patient PCPs. How many patients have a PCP? Do all patients know who their PCP is? Do all patients...
know what “PCP” refers to? Is patient-reported PCP information reliable? What should we do when the PCP information is missing? The specific objectives of this study were to a) understand patient-reported PCP information, b) demonstrate the feasibility of using EHR data to impute a patient’s PCP, and c) compare the imputed PCP with patient-reported PCP.

Methods

Setting

Intermountain Healthcare (hereafter referred to as “Intermountain”) is a not-for-profit health system based in Salt Lake City, Utah that operates 22 hospitals, over 185 clinics, a broad range of laboratory and pharmacy services, and an affiliated health insurance company. Intermountain has about 1,400 employed physicians and 3,000 affiliated physicians. It is the largest integrated health system in the Intermountain West region of the United States.

Data Source

Data for this project included enterprise-wide inpatient, outpatient, and emergency department registration and encounter records at all Intermountain facilities.

Registration Dataset

To understand the characteristics of patient-reported PCP, we analyzed the registration data generated from two patient registration applications—one for hospital and emergency department encounters (R1) and one for outpatient clinic encounters (R2). R1 requires the registrar to collect encounter-based PCP information, which means that the patient needs to declare his/her PCP at each visit, regardless of whether the PCP information has been collected previously. R2 treats PCP as longitudinal data and allows the registrar to keep or update the PCP information if the patient has reported a PCP during previous visits. However, in R2, new PCP information simply overwrites the old information and current data do not support the analysis of a patient’s PCP history. R2 also allows the registrar to enter the reason for missing PCP. We extracted registration data from both R1 and R2 during a two-year period between September 1, 2014 and September 1, 2016.

Encounter Dataset

To examine the feasibility of using EHR data to impute a patient’s PCP, we analyzed patient encounter data to extract all patient-provider interactions during a five-year period between September 1, 2011 and September 1, 2016. The encounter dataset included all ambulatory visits at any Intermountain facilities. Inpatient hospital visits and emergency department visits were excluded based on the assumption that hospitalists and emergency medical doctors focus on individual encounters and do not establish a longitudinal relationship with a patient. Each encounter record included in the analysis consisted of a unique patient-provider encounter record included in the analysis consisted of a unique patient identifier, the provider’s identifier for that visit, and time and location of the visit.

We linked the registration dataset and encounter dataset with our internal provider directory that includes both Intermountain-employed providers and independent practitioners who are affiliated with Intermountain. Many of the independent practitioners have privileges to admit patients to an Intermountain hospital. However, they usually have separate patient registration and EHR systems for outpatient visits. Each record in the provider directory included a provider’s full name, specialty, employment status, practice location, phone number, fax number, etc. However, many records in the provider directory were identified with incomplete information.

External Dataset

Considering the fact that patients frequently visit providers from multiple healthcare organizations, we extended the imputation analysis to statewide encounter data outside of our health system. We extracted all clinical messages received by the state Health Information Exchange (HIE) from major hospitals, clinics, labs and insurers in Utah between 2011 and 2016. The types of clinical messages included admit, discharge, and transfer (HL7 ADT), laboratory, radiology and transcription results, and prescriptions (HL7 Pharmacy/Treatment Encoded Order Message—RDE). Each clinical message extracted for this study consisted of a unique HIE patient identifier, provider information in the Patient Visit Information (PV1) segment, and date of service. The HIE patient identifier was linked to the Intermountain patient identifier through the community master patient index.

Analysis

The first part of the study was a descriptive analysis to characterize patient-reported PCPs. We analyzed the completeness of PCP information declared by patients or family members. We also analyzed the consistency of PCP declared across encounters for the same patient using the registration data from R1. Reasons for missing PCPs were summarized.

The second part of the study was to impute the primary provider for a subset of patients who had inpatient or emergency department encounters between September 1, 2014 and September 1, 2016. The imputation algorithm leveraged all records extracted into the encounter dataset and calculated a closeness score for each patient-provider pair using Eq.1 was an updated algorithm from our previous work [12]. The underlying design principle of our imputation algorithm is the more frequent and more recent a patient was seen by a provider, the higher the closeness score between the patient and the provider. Most existing attribution rules employed by health insurers are also based on this principle. However, these rules only use the date for the most recent visit when there is a tie between multiple providers. We further refined the algorithm by taking into account the date of each previous visit. Each patient-provider encounter record was assigned with a score that was inversely correlated to the lapsed time between the current date and the date of the encounter. The “current date” (denoted as “date of the target visit” in Formula (1) refers to the time when a provider is imputed based on all previous encounters. The sum of all visit scores for a unique patient-provider pair was the total score for that patient-provider relationship. A threshold (closeness score=2) was defined to identify the providers who were considered as the primary provider. The parameters k and e in Eq.1 and the threshold were chosen based on iterative adjustments in order to make the algorithm clinically intuitive.

\[
\text{closeness_score} = \sum_{i=1}^{n} e^{-k(T-t_i)}
\]

where

\(n=\text{total number of encounters;}
\]

\(k=0.001;
\]

\(T=\text{date of the target visit;}
\]

\(t_i=\text{date of the }i^{th}\text{encounter}
\]

We compared the imputed primary providers with patient-reported PCPs for two subsets of patients: 1) patients who had more than one inpatient or emergency department encounters during the study period and declared the same PCP across
multiple encounters, and 2) patients who had inpatient or emergency department encounters during the study period and did not declare a PCP at the encounter. Step 1) was to understand the strength and weakness of the imputation algorithm. Step 2) was to demonstrate the potential value of the imputation algorithm in identifying primary providers to be notified for inpatient and emergency encounters when the PCP information is missing.

Results

There were 2.5 million registration records for about 830,000 patients generated from R1 between September 1, 2014 and September 1, 2016. R2 had about 1 million registration updates during the two-year period.

Completeness of Patient-reported PCP

Table 1 shows the completeness of patient-reported PCP information by encounter type. About 58% of all inpatient encounters had some PCP documented during registration and 52% for emergency visits. Inpatient Behavioral health encounters had the lowest PCP declaration rate (24%). Outpatient registrations had the highest PCP declaration rate in general (74-89%). For patients who reported PCPs, the PCP information was not consistent across encounters. Among all inpatient and emergency encounters generated in R1, 31% of the patients had more than one encounter during the two-year period, only 27% of whom reported the same PCP across multiple encounters. Over 5,000 patients had more than five PCPs reported and the maximum number of PCPs reported by a patient (or family member) was 15 during the two-year period.

</table>

*The outpatient registration records were extracted from a combination of R1 and R2. The overall proportion of outpatient PCPs does not apply here.

For patients with missing PCP during registration, only 0.2% had a reason documented. About a third of these patients reported that they did not have a doctor they see regularly, and 5% of the patients did not remember or only remember partial information about their PCP (Figure 1). Very few patients did not want to disclose their PCP information and did not want the hospital to forward the discharge summaries to their PCP.

Provider Profiles

The top ten primary specialties of patient-reported PCPs are illustrated by the dark grey bars in Figure 2. Eleven percent of patient-declared PCPs were Family Medicine doctors, followed by Physician Assistants (6%). Surprisingly, Emergency Medicine doctors and Dentists were at the top ten most popular PCP specialties reported by patients. Due to the data quality issue of the provider database, not all providers have a primary specialty recorded. One percent of patient-reported PCPs were non-person accounts (e.g. facilities or clinics). Forty percent had an inactive status at the time of query. Eighty-one percent had either a phone number or fax number recorded in the provider directory. However, our analysis did not validate the phone number and fax numbers.

Algorithm-imputed PCPs

Firstly, we conducted the imputation algorithm on patients who reported the same PCP across multiple encounters during the
two-year period. The results showed that the algorithm identified one or more primary providers (closeness score >= 2) for 62% of the patients and 38% of the imputed providers were consistent with patient-reported PCPs. Table 2 shows some example closeness scores calculated by the imputation algorithm using the “Target Visit Date” as the reference point of time. Any visit occurred before the target visit date was counted in the closeness score. As shown by the highlighted rows for pt001, even though the number of visits with pv102 exceeded the number of visits with pv101, the closeness score for pv101 was higher since the visits were more recent.

For those patients who did not get an imputed provider, we manually reviewed some randomly selected patients’ chart. As expected, the primary factor was that these patients only had emergency visits at Intermountain. Reported PCPs from these patients were independent practitioners who were not employed by Intermountain. As a result, the visit history was captured by the doctor’s own EHR that was not part of the analysis dataset.

By applying the same imputation algorithm from Formula 1, we identified the primary provider for an additional 15% of the patients. As shown in Table 3, the completeness of the provider information contained in the PV1 segment of the HL7 messages was between 1% and 17%.

![Image](https://example.com/image)

**Figure 4 – Clinical messages received by the state HIE on sample patients**

### Discussion

Our study suggest that PCP information is not well-documented in EHRs. Only about half of the inpatient and emergency encounters have PCPs reported by the patient or family members. For certain types of encounters such as behavioral health inpatient stays, the completeness of PCP information can be as low as 24%. Missing, incomplete or outdated PCP information can become the bottleneck to effective physician communication and care coordination, especially during transition of care. Based on our analysis, the reasons for missing PCPs were multifaceted. There may not be sufficient time to collect the PCP information during registration. Some patients may only remember their PCP’s last name or practice clinic.

For patients who reported a PCP during registration, it is not clear how reliable the PCP information is. As shown by our provider profile analysis on patient-reported PCPs, some patients declared an emergency doctor or dentist as their PCP. This may indicate that patients or family members do not understand what a PCP refers to. As part of the care coordination and outreach effort, Intermountain has been instructing designated staff to collect PCP information by visiting patient rooms at an inpatient facility if the PCP information was not documented during registration. We found that sometimes the hospital staff needs to ask the question in several different ways to explain what a PCP is. For example:

- **Which doctor do you usually see for your annual visit?**
- **Who ordered your medications?**
- **Who do you want us to send your discharge information and lab results to after you go home?**

### Imputation Results from External Data

Considering the limitations of Intermountain-only encounter data, we conducted a preliminary analysis on a subset of patients (2,600) who had an inpatient stay at one of the Intermountain facilities between June 2015 and February 2016 and did not specify a PCP at registration. We queried the state HIE database to extract all clinical messages that indicated a patient-provider encounter. Results showed that 71% of the patients can be matched in the HIE dataset. A total number of 26,888 messages were received from 37 healthcare organizations on 693 (27%) patients. The distribution of message types is illustrated by Figure 4.

**Note**: all identifiers and dates were de-identified without affecting the trend of the algorithm.

Secondly, we applied the algorithm to patients who did not have a PCP declared at the inpatient or emergency encounter during the study period. The purpose of the second part of the imputation analysis was to demonstrate the feasibility of identifying the appropriate provider who should be notified about a hospital stay or emergency visit when the PCP was not collected from the patient. Results showed that the algorithm could identify one or more primary provider for 38% of the encounters.

We further compared the primary specialty and employment status of the algorithm-imputed providers with the patient-reported PCPs. As shown in Figure 2, the top 5 specialties for imputed providers aligned with patient-reported PCPs. Dentist, resident and emergency medicine did not have or had very low representation in imputed providers. Figure 3 shows that the imputed providers were more likely to be Intermountain employed. This can attributed to the input dataset used by the algorithm.
Our imputation analysis demonstrates a promising approach to infer a patient’s primary provider based on encounter history. This will greatly benefit patients discharged from hospitals or emergency departments whose PCP was not captured during registration. The imputation results only showed 38% consistency with patient-declared PCP. There are several reasons for this: 1) Patient-reported PCPs are not the gold standard. It only reflects patients’ perceptions, which may not be reliable as indicated by various findings in the study. In other words, the algorithm-derived primary providers may be more accurate since they are based on the actual patient-provider interactions; 2) The performance of the imputation algorithm depends on the comprehensiveness of the patient-provider encounter dataset as input. We only used enterprise wide encounter data for the first part of the analysis to infer the primary providers for 62% of the patients. As we extended the input to include state wide data, it increased the proportion by 15%.

Our study also suggests that the lack of a statewide or national provider directory is a limitation preventing both PCP information collection from patients and PCP imputation by the algorithm. A complete and up-to-date provider directory will facilitate provider lookup when the patient could not remember his/her PCP’s full name, especially when the provider is outside of the health system. Most healthcare organizations maintain their own provider directory, which normally has up-to-date information for internally employed providers. However, as the adoption of interoperable health information technology such as Direct messaging [13] increases, the need to maintain providers from external organizations and their communication preferences grows. Currently, many hospital units maintain a separate list of commonly interacted providers (e.g. referral doctors) with phone number, address and fax number in a spreadsheet file. Some healthcare organizations exchange provider list that contains Direct email addresses with their partner organizations on a regular base. A formal provider directory management infrastructure could help to overcome the duplicate and uncoordinated efforts required from individual organizations.

Limitations and Future Work

The major limitation of our study is the lack of external encounter data as input to the imputation algorithm to infer PCPs outside of Intermountain. Although we conducted a preliminary analysis using the state HIE clinical messages received from other healthcare providers, the missing values in the provider information segment of the HL7 messages limited the performance of the algorithm. In addition, for those HL7 messages with provider information, there is no unique provider identifier across organizations. Each organization used its own provider identifier and some HL7 messages only had provider’s name without an identifier.

Nevertheless, our analysis demonstrated feasibility of using EHR data to infer a patient’s PCP. It is important to note that algorithmic imputation should not overwrite patient’s preferences. The purpose of the imputation algorithm is not to replace patient-reported PCPs but to serve as a complementary mechanism to support accurate PCP information collection. As future work, we plan to display the imputed primary provider(s) in the registration systems and patient portals to allow patients to confirm or modify the list and specify their information disclosure preferences. PCP is longitudinal information and should be maintained across encounters regardless of the care setting. We plan to test the algorithm with other healthcare organizations and design a community care team framework to allow organizations to share the imputed provider information through an ongoing statewide care coordination effort [14].

Conclusion

Effective and seamless communication with primary care physicians during the discharge period is pivotal to boosting patient safety and reducing the likelihood of avoidable readmissions. Our findings suggest that complete and reliable PCP information may not be available in EHRs and associated administrative systems. Lack of PCP information may hinder collaboration among physicians and delay timely follow-up. We demonstrated the feasibility of using historical encounter data that is easily accessible in any EHR to infer complementary provider information when a self-reported PCP is missing or invalid. Our methods can be generalized to any healthcare organization to improve the availability and accuracy of PCP information for care coordination purpose.

Abstract

Large population studies are important sources for medical research. These studies are well planned, well organized, and costly. However, people record health data themselves using different sensors, which are mostly unplanned, unorganized and inexpensive. Nevertheless, self-recorded data might be an important supplement to population studies. The question is how to access and use this data. In the seventh survey of the Tromsø cohort study, questionnaires and accelerometers were used to collect data on physical activity (PA). We now plan to collect historical PA data from these participants, using mobile sensor data already stored in the cloud. We will examine the feasibility of this approach and the quality of this data. Objectively measured historical data will provide valuable insights in the potential and limitations of mobile sensors as new data collection tools in medical research.

Keywords:
Cohort studies; Human Activity; Fitness Trackers

Introduction

The Tromsø Study is a large ongoing population based study in the municipality of Tromsø, Norway. Researchers have conducted repeated surveys 5-8 years apart for a period of 40 years. The Tromsø Study was initiated in 1974 to understand the reasons for the high prevalence of cardiovascular disease in Norway, as well as to find ways to prevent and intervene [1-2]. Since then there have been six additional surveys. In the most recent survey (2015-2016), the seventh Tromsø Study (Tromsø 7), everyone above the age of 40 was invited. More than 21,000 people participated (65% attendance rate) and went through a wide range of examinations, including questionnaires and interviews, physical and clinical examinations and biological sampling. There are more than 50 different research projects in Tromsø 7, several of which uses PA as a predictor, endpoint or adjustment variable.

In all seven surveys, participants completed a questionnaire, including questions about PA. In Tromsø 7 there were six questions related to PA (sedentary behavior, occupational and leisure-time PA, and PA frequency, duration and intensity).

In the sixth Tromsø Study (2007-08), a subsample of 300 participants wore an accelerometer for seven days, to obtain objectively measured data on PA. Although the coinciding questionnaire was previously validated as a tool to collect data of high-intensity leisure activity, it was also shown that moderate-intensity leisure activity was over-reported when compared to the objectively measured data [3].

In Tromsø 7, 6,300 participants wore the ActiGraph wGT3X-BT accelerometer for one week. A subsample of 700 participants wore the CamNtech Actiwave Cardio for 27 hours. With these sensors, researchers were able to objectively measure PA, energy usage, sedentary behavior, and sleep. The Actiwave Cardio also measured a single lead ECG giving data on heart rhythm and heart rate.

Since PA is an important life style factor, data collected from accelerometers will be important in several ongoing projects. Combining self-reported PA data with objectively measured PA using accelerometers enhances validity in PA measurements. However, having access to continuous PA data over an extended period can be a valuable addition to the data already collected. The next step is to collect historical PA data for participants in Tromsø 7.

Most people carry a smart phone with them throughout the day [4] and a lot of people also have an activity tracker in form of a smart watch or activity bracelet [5]. These devices have several sensors that can measure PA. Android and iPhone users can opt to upload collected health information to Google Fit or Apple HealthKit, which are cloud-based services that allows device vendors and application developers to store health related information in a common online location. This can be beneficial for users, because they can access this information and see details and summaries for all kinds of health related information in one application. A wide range of health related data types can be stored here, but in this project, we will only look into how to access PA and heart rate data.

Compared to the ActiGraph, PA data collected from mobile sensors and connected smart devices are not equally validated for all types of measurements. A systematic review from 2015 indicates that validity of step counting was high, whereas energy expenditure and sleep had a low validity [6]. Validity on PA was inconclusive because of few available studies. In this review, they only considered FitBit and Jawbone, the two leading vendors in the consumer market in 2015. Newer studies seem to indicate the same results [7-8]. Two studies [9-10] from 2016 also indicate that modern wrist worn heart rate monitors are accurate and therefore relevant for our study. Moreover, there will be gaps in the data for participants who do not have a wearable fitness tracker, because not everyone carries their smart phone at all times. These limitations are not necessary drawbacks, but they need to be well understood.

In this vision paper, we will present our plans for retrieving historical PA data, by accessing Google Fit and Apple HealthKit cloud services, for users with smart phones and activity wearables. We will only invite people who participated in Tromsø 7, because their data can enhance existing data sets for Tromsø 7 participants, as well as allow us to examine...
the feasibility and quality of this data compared to subjective and objective PA measurements.

**Methods**

**Cloud-Based Health Repositories**

On September 17, 2014, Apple released HealthKit. Google released Fit on October 28, 2014. Users can activate these services to track and store PA, heart rate, diet, sleep patterns and other health metrics. It is possible for users to input information manually, it can be added by third party applications, or it can be automatically collected from internal phone sensors and sensors in connected smart devices (i.e. watches, bracelets, etc.). Users can later view this information or share it with other applications to get a better overview of their health status.

“Google Fit is an open ecosystem that allows developers to upload fitness data to a central repository where users can access their data from different devices and applications in one location” [11]. Google Fit is supported by Android 2.3 and above and consists of four components: 1) the Google Fitness store, 2) the sensor framework, 3) permissions and user controls, and 4) the Google Fit APIs. There are six APIs and the History API and the Sessions API allows access to historical data and can be used to access relevant information [12-13]. Users can specify what they want to share with the different applications.

Apple HealthKit was introduced in iOS 8 and provides a “centralized, coordinated, and secure data store for health-related information” [14]. There are three ways to access fitness information through the HealthKit API [15]. The query approach is appropriate for extracting snapshots of specified periods within the store. These snapshots contain, among other things, aggregated data like step counts.

It is possible to export health data manually from Google Fit, either from the Google web sites or the Google Fit application. Supported formats include TCX-files and CSV-files. TCX-files (Training Centre XML) are a specialized XML format for transferring heart rate, training pace, calories, GPS and other PA related information. Apple HealthKit also supports manual export to XML-files and CSV-files. Exporting data manually from these services is cumbersome and not a straightforward process for all users. It is however, a way to download the data without writing any code, and we can therefore use it as a quick way to access sample data during development and testing.

We do not know how many Trotmso 7 participants who actually use these cloud services, when they started using them, how often and what type of information they add or how accurate this information is. However, among the more than 21,000 participants in Tromsø 7, it is likely that several have used these cloud services for some time. Furthermore, 83% of the population in Norway have a smart phone [4] and it has been estimated that more than one million smart bracelets and watches will be sold in Norway in 2016 [5]. This is in addition to the 720,000 bracelets sold in 2014 and 2015 [5].

**Information Flow**

In the proposed solution, we will create a two-part system. In addition, some enhancements on an existing system are required. The first part is a mobile application that will collect and forward health data to the second part. The second part is a Web Service (WS) that will collect, process and forward data to an existing system called EUTRO. EUTRO is the main storage for research data in the Tromsø Study.

Figure 1 shows a simplified illustration of the information flow in this solution. Every time an authorized health application or device receives data, it can also store (1) this data in the Apple HealthKit (A) and/or Google Fit (B) cloud services. This data can be accessed by other authorized applications and the proposed application (C) will be installed on participant’s phones, so that this information can be downloaded (2) from the two cloud services. The data will then be uploaded (3) to EUTRO, via the WS, connecting the data to the correct participant in the Tromso Study.

![Figure 1-Information flow](image)

**System architecture**

The proposed system can collect data from potentially thousands of participants, process this data into usable information, and forward it to EUTRO.

Figure 2 illustrates the architecture for this system.

*Internal phone sensors* and *smart device sensors* generates data which, in addition to manually entered health information, can be shared with *third party health applications* and/or stored in the Apple HealthKit/Google Fit application running on the user’s phone. The Apple HealthKit/Google Fit application will forward this information to the appropriate cloud service. *Third party health applications* can also forward this data to other devices or application specific cloud services.

Participants must install the *Tromsø Study application* on their phones. This application will, upon user authorization, access relevant health data from Apple HealthKit and Google Fit cloud services. After authorization, the participants must enter a unique number, identifying them as participants in Tromsø 7. This allows linkage of new data to existing data for study participants. Participants will also be able to specify which health data the application can access.

In addition to health data, it is important to have access to sensor and device meta-data. This is necessary in order to examine the data quality, and to examine whether this data collection strategy is a feasible method for collecting objective PA data. After the data transfer to the Web Service in the Tromsø Study backend is complete, participants can uninstall the Tromsø Study application. We are only focusing on historical data in this study and will only download data once. Future PA data is not part of this solution.

The *Web Service* receives the data and processes it into information that can be stored in EUTRO. Depending on what data participants have stored in the cloud services, it is possible to store a range of different information. Examples include daily step count, calories burned, heart rate, workouts, sleep patterns...
and more. The Web Service will forward the processed information to EUTRO, where it is stored and made available for active projects in the Tromso Study.

**Figure 2-System architecture**

We can potentially invite more than 21,000 participants, so it is important that the system scales. Not everyone will connect at the same time, but the amount of available data can be extensive, depending on how much data participants have stored in the cloud and how much they are willing to share.

**Mobile application**

Our goal is to develop Android and iPhone applications that can read PA and heart rate data from these cloud services. To avoid having to create multiple code bases, we will write the application once and compile it for two platforms. Several solutions allow this. One promising alternative is React Native by Facebook [16], which makes it possible to program the application in JavaScript and compile two versions, one for Android and one for iPhone. React Native also supports coding natively, which we will need in order to access the two cloud services.

Through the application, participants can specify which data they agree to transfer, as well as from which period they want to share data. It is not possible to run one query to return everything. Each type of data must be accessed and transferred individually. It will therefore take some time to collect and transfer the data. Ideally, participants will be willing to share all available data, but because some participants may be reluctant to share everything, they will get the option to specify what they share. Although the amount of data and the level of details for each participant will vary because of this, we hope this will result in a higher participation rate. Figure 3 shows a mock-up of the proposed mobile application, where the user can select what to share and from which period they want to share data.

**Figure 3-Mobile application mockup**

EUTRO

Data collected in the Tromso Study is stored in EUTRO, a system for managing research projects, biological material, health data and meta data [17-18]. Historical PA data must also be stored here. EUTRO does not currently have an interface for receiving information from mobile applications or other external systems. This means that EUTRO must be extended with an interface to receive data from the new WS, which will serve as an intermediate server for collecting and processing data from the mobile application, as well as a prototype for the changes needed in EUTRO. Until EUTRO is updated, collected data can be manually imported into EUTRO using existing features.

**Web Service**

The mobile application’s only function is to transfer health data from the two mentioned cloud services. The planned WS will be the most complex part of the system. This is because the transferred data will be of different types, have different detail levels and be from different periods. This data must be processed into usable and comparable information.

The data that is most likely to be available is step count data, which might be aggregated hourly, daily, weekly or monthly, or averaged over a longer period.
The following types of health data will be collected, processed and forwarded, if they are available:

- Daily, weekly and monthly step counts
- Daily, weekly and monthly average step counts
- Daily, weekly and monthly average heart rate
- Sedentary behavior
- Sleep patterns
- Exercise bouts, including detailed heart rate, intensity, average speed and inclination
- Estimated precision on each data set
- Sensor meta data

Security is important when working with health data. Information transferred between systems will be encrypted using SSL. Authentication is achieved by using a unique identification number included in the invitation letter. When the mobile application has completed the data transfer, it will call a method to disable the identification number. This will further enhance security. The WS will be REST-full, that is, stateless and self-contained, encouraging a simple, lightweight and fast interaction between server and client. This is important to support the high number of potential participants.

**Challenges**

There are several challenges in this project. Motivating participants to install the application in order to share their information, is probably going to be the main challenge.

Wearing an ActiGraph, a standalone physical device, not connected to anything is one thing. With the ActiGraph, it was expected to be challenging to motivate participants to wear the device for several days, because of the inconvenience it might cause. However, compliance among participants in Tromsø 7 was high, with a 94% acceptance rate. Installing an application with the purpose of sharing personal health related data is another thing altogether. There are several challenges with this approach where trust and motivation probably are the two most important.

Installing any application on your personal phone, where you have so much personal data stored, requires a certain level of trust. There are many fraudulent applications which only function to hijack your phone and access your personal information. As a participant, you must trust that the application only does what it claims it will do. Specifically, that the application will only access data the participant has agreed to share, and that the system is secure and data interception is impossible during transfer.

We need to find ways to motivate participant to share their data. The Tromsø 7 survey contained questions, tests and measurements, divided into two phases. Those attending both phases have already spent about 4 hours contributing data to Tromsø 7. Participants in the PA project, wearing the ActiGraph for a week, have contributed even more. Asking participants to use more time can potentially be a challenge. However, because the effort needed to share data is very low, once the application is installed, we are confident that many will be willing to participate in this extension to the PA project. After installing the application, participants only have to input an identification number and select which data to share. The rest is automatic and requires no additional input.

However, installing the application and using it properly can be a challenge for some participants. In a future survey, it is possible to set up a station where people can get assistance with the setup. Because the data collection phase of Tromsø 7 is completed, there is no infrastructure to provide such assistance now. This will be resolved by making a detailed instruction that must be included in the invitation letter. In addition, making an instruction video might result in some additional participants.

**Ethics**

Actively installing the application and selecting which data to share requires informed consent from all study participants. We will apply for recommendation from The Regional Committee for Medical and Health Research Ethics, and for approval from the Norwegian Centre for Research Data on the processing of personal data.

**Expected Results**

**Scenarios**

The most likely scenario is a person who only has a mobile phone and no wearable smart device. For this person, only a limited set of data will be available, and only in periods the person has the phone with him/her. For several hours of the day, as well as during the night, the internal mobile sensors will not collect any activity data. In this scenario, we expect that the system will get access to daily step count, which is unlikely to be accurate because the phone is not carried around all day.

A more data rich scenario will be a person that has an activity bracelet or watch that also can collect heart rate. For this person, it will be possible to collect heart rate data for specific days, as well as to compare this data with different levels of PA. If this person brings a GPS-enabled phone during workouts, or has GPS built into the bracelet/watch, it will be possible to access average speed, max speed, altitude differences, average heart rate, peak heart rate and more. As an example, measuring how the heart rate recovers after exercising is an indicator of cardiovascular health.

**Data Usage**

The information collected from participants in Tromsø 7 is extensive. All study participants completed comprehensive questionnaires, sharing information about their lifestyle, general health, medical history, drug usage, diet, alcohol consumption, smoking, education, social status, PA and other areas. Measurements of height, weight, hip-waist, blood pressure, heart rate, SpO2 and pain sensitivity were also collected. Biological samples of blood, saliva, urine, feces and samples from the nose/throat were also taken. A subsample underwent dental examinations, ECG-recording, cognitive tests, physical function tests, carotid ultrasound, eye tests, lung function tests, measurements of bone densitometry and body composition (by DEXA), echocardiography, and heart-, lung- and carotid auscultation. Many of the participants also attended earlier surveys in the Tromsø Study, which gives the possibility to analyze repeated measurements, enriching the data further.

Because the validity of the data collected by wearable devices is unknown or low for most data types related to PA, step count data will be collected first. Heart rate data for participants using heart rate monitors will also be collected since these sensors are considered accurate. Participants who already wore accelerometers in Tromsø 7 will be invited first. With these participants, existing accelerometer data can be compared with participant’s phone and wearable sensors collected in the same period. This will help determine how accurate step count and heart rate data collected from these sensors are. If accurate, all remaining participants in Tromsø 7 will be invited. This will potentially result in objective measurements for step counts for a proportion of the 21,000 participants in Tromsø 7.
Discission

PA is an important lifestyle factor and is relevant in multiple projects in Tromsø 7, both as a predictor, endpoint and adjustment variable [19]. Data from accelerometers include heart rate, PA, sleep patterns, energy usage and sedentary behavior. However, only one week of PA data was collected using accelerometers. To get a broader picture of PA in a population, it is of interest to include historical PA data stored in Google and Apple cloud services. Data from accelerometers used in Tromsø 7 is considered accurate. This level of accuracy is, for the most part, not achievable through mobile and smart device sensors.

Participants will have a wide range of mobile devices, resulting in data from a wide range of different sensors. For those wearing a smart watch or bracelet with activity and pulse sensors, there will also be a lot of variety in how accurate these sensors are. Until data collection starts, the accuracy of the data is unknown. In addition, from participants that do not have a smart watch or activity bracelet, activity data will only be available for parts of the day. All these limitations are okay, if we know about them. The data should not be used alone, but rather as supplements to the data already collected in Tromsø 7.

Population based studies are valuable sources for new knowledge and for monitoring the status and development in population health and for disease risk factors. However, these types of studies are costly, and epidemiologists are concerned that participation rates are declining both in Norway and internationally. Hence, we need to motivate study participation and develop new tools for data collection. Smart phones come forward as promising data collection tools. They are prevalent, it is easy for study participants to donate their data, and large amounts of data can be collected from many study participants at a low cost.

Physical inactivity is an emerging and important disease risk factor in western populations. We aim to develop solutions to access data on PA from smartphones using internal and connected sensors.

Future Work

Collecting historical data is only the first step in including PA and heart rate data from mobile sensors in the Tromsø Study. The next step will be to collect the same kind of data for future activity. That is, to collect all PA and heart rate data for several months using mobile sensors and sensors in smart watches, bracelets and other smart devices. The experience from accessing historical data will be valuable going forward. After implementing the system described in this paper, we will expand the system design into a solution for collecting future data.

Conclusion

In this paper, we described our plans for collecting up to two years of historical PA and heart rate data from participants in the Tromsø 7 survey. Accessing this data is possible through Google Fit and Apple HealthKit cloud services. Access is restricted, and participants must consent to donate their data to the Tromsø Study database. The quality of the data is unknown and we therefore wish to examine it. The data will be a supplement to existing PA data from accelerometers and questionnaires in Tromsø 7. In order to validate these sensors as potential new tools for objectively measure PA, we will compare data collected from mobile sensors with existing accelerometer data.

Abstract

The rise of health consumers and the accumulation of patient-generated health data (PGHD) have brought the patient to the centerstage of precision health and behavioral science. In this positional paper we outline an interpretability-aware framework of PGHD, an important but often overlooked dimension in health services. The aim is two-fold: First, it helps generate practice-based evidence for population health management; second, it improves individual care with adaptive interventions. However, how do we check if the evidence generated from PGHD is reliable? Are the evidence directly deployable in realworld applications? How to adapt behavioral interventions for each individual patient at the touchpoint given individual patients’ needs? These questions commonly require better interpretability of PGHD-derived patient insights. Yet the definitions of interpretability are often underspecified. In the position paper, we outline an interpretability-aware framework to handle model properties and techniques that affect interpretability in the patient-centered care process. Throughout the positional paper, we contend that making sense of PGHD systematically in such an interpretability-aware framework is preferable, because it improves on the trustworthiness of PGHD-derived insights and the consequent applications such as person-centered comparative effectiveness in patient-centered care.

Keywords:
Informatics; Patient-Centered Care; Machine Learning

Introduction

Owing to the trends in participation health [1] and value-based care [2], health consumer perception and adoption of direct-to-consumer devices and sensors and citizen science are at all-time high.[3] Meanwhile, more and more leading healthcare systems are evaluating the secondary use of patient-reported outcomes measures (PROM) in electronic health records (EHR).[4] A plethora of patient-centered data generating devices and care processes are producing masses of data.

The early evidence has started to emerge and stimulate the field through best practices.[5] As shown in Figure 1, many of the healthcare applications hinge on the convergence of PGHD and clinical data, as well as the clinical and patient information system. This is in line with the vision of patient-centered care as defined in a recent patient advocacy testimonial in Health Affairs [6] as “the experience (to the extent the informed, individual patient desires it) of transparency, individualization, recognition, respect, dignity, and choice in all matters, without exception, related to one’s person, circumstances, and relationships in health care.”

In particular, two opportunity areas emerge. First, PGHD helps generate practice-based evidence for population health management.[7] Traditionally, clinical evidence is generated from costly randomized controlled trials (RCT) and comparative effectiveness studies in observational clinical data such as EHR, claims and administrative databases. However, as indicated in the recent Institute of Medicine (IOM) report [8], it is important to start designing clinical information systems that can help capture the patient’s state such as social, behavioral and environmental determinants, while fitting situational use of PGHD-derived evidence in the clinical context.[4,6]

Second, PGHD improves individual care through adapting interventions against the incoming stream of patient observations (e.g., lifestyle and physiological measures) and outcome history. The initial results show potential in making sense of PGHD for clinicians and care coordinators [9,10] and fitting situational use of PGHD (for example, for adaptive trials of mobile app-based behavioral interventions [11]).

Both opportunity areas lead to many subsequent questions regarding the interpretability of PGHD in real-world healthcare applications. For example, how do we check if the chunks of evidence generated from PGHD are reliable? Are they directly deployable in real-world healthcare applications? How to adapt the behavioral interventions for each individual patient at the touchpoint given individual patients’ needs? Despite the recent attention in developing interpretable machine learning models for healthcare applications [12,13], the definitions of interpretability are underspecified due to the many different motivations.[14]
Method

In this positional paper, we hereby first review the major dimensions underneath the interpretability mentions. Then, we address the next challenge for the development of health informatics tools to enhance the interpretability-awareness of PGHD-derived insights. We summarize the various issues and model properties that should be addressed in an interpretability-aware framework (as shown Figure 2 below). Next, we highlight the emerging practices in which the framework provides value to patients and clinicians and improves care delivery. Finally, we examine present and future challenges to incorporating PGHD-based evidence back into the care flows, and utilizing cleansed and approved data for purposes beyond their primary context and motivation of collection.

![Interpretability-aware framework for population evidence discovery and individual intervention adaptation](image)

**Figure 2– Interpretability-aware framework for population evidence discovery and individual intervention adaptation**

**Summarizing Major Dimensions of Intepretability from Patients’ Perspective**

To understand major dimensions behind interpretability, we need to first review the motivations of improving interpretability in different dimensions. For example, [15] explains and quantifies the interpretability metrics for decision rule-based analytics. Here are a few dimensions that we identified for applying machine learning models to generate practice-based evidence and adapt interventions for individuals.

**Complexity:** As noted in [16], humans are best able to reason about models that are composed of simple forms such as decision trees.[17,18] This interpretability constraint on model complexity persists when it comes to generating N-of-1 models to tailor intervention recommendations. In practice, this involves further constraining policy learner architectures to limited sets of simple rules – first at the population level, and then at the individual level. This has inspired a variety of methodological advancements recently. For example, combining reinforcement learning and regression trees can produce simpler policies for human inspection.[19] Recent results suggest that simple explainable policies could be achieved in complex problems, such as fine-tuning adaptive evaluation of behavioral intervention strategies.[11]

**Knowledge Structural Similarity:** The interpretability can also be defined as a distance metric based on the known domain information. Intuitively, closer the concepts covered by PGHD, easier is their interpretation. Suppose there exist some relationships among the features defined in a hierarchical manner as represented by a tree or directed acyclic graph. The inherent hypothesis is to make sure that the similar features should have similar model co-efficients learnt by the model. One popular approach is group LASSO [20] based techniques, which can pose additional constraints on the above equation to make sure that all the nodes rooted in a particular subtree will have similar parameters during model learning.

**Quality:** Another major hindrance of patient interpretation of data is the quality issues of PGHD. The sources of errors in PGHD is multi-fold. For self-reported data, the baseline of patient-reported outcome and lifestyle information (for example, daily calorie intake) varies from person to person, resulting in under-reporting or over-reporting. Moreover, the measurements from health wearables and IoT (Internet-of-Things) sensors are often noise corrupted due to inappropriate placement, incorrect use, regular wear and tear of the devices.

To overcome the data quality issues, the process of imputing missing values and detecting anomalies and outliers are then needed to train models; which in turn is used for forecasting.

**Usability:** HCI researchers conducted qualitative studies (e.g., [21]) to make sense of patients’ own data and in addition, to identify interpretability-impeding factors, including: confounders, noisy on meaningful and irrelevant measures, and how to determine the time lag of outcome affecting triggers at the individual level.

**Causality:** To further ensure that the framework can provide statistically sound interpretation, we surveyed the causal inference research to understand the effect of following assumptions [22]: consistency (i.e., whether one’s features and outcomes are consistently observed when the actions are taken), stability (i.e., whether one’s features and outcomes are affected by other subjects’ actions), and unmeasured confounders (i.e., what is the sensitivity of conclusions with factors that influence the assignment of treatments).

The survey leads us to believe that there exist quite diverse views behind the concept of interpretability, and the field of health informatics needs to reconcile the differences by first making the previously implicit assumptions more explicit.

**Developing Interpretability-Aware Framework**

The development of the interpretability-aware framework is based on a two-layer approach: (1) “Learn from Big data”: PGHD from heterogeneous sources are aggregated to learn practice-based evidence for optimal outcome (e.g., efficiency of patient capacity) and (2) “Adapt with Small data”: interpreting evidence through comparing the effectiveness across interventions and adapting in a patient-centered way.

**Learn from Big Data: PGHD to Practice-based Evidence**

First, in order to learn interpretable practice-based evidence that can be conferred from the secondary use of PGHD, we need principled and scalable approaches to address the interpretability issues: model complexity and knowledge structural similarity. The goal is to minimize the model complexity during the process of interpreting model parameters, while boosting knowledge structural similarity to account for prior knowledge during model development.

**Interpreting Model Parameters:** Most informatics tools rely on learning a set of parameters that are associated with the features extracted from raw PGHD. In particular, an objective loss function is defined based on the original model outcomes and the predicted outcomes using the parameters of the model and then, those parameters are learnt from PGHD such that the loss function is minimized. Let $X$ denote the original feature set, $y$ the outcome, and $W$ the model parameters. The loss function can be represented as below:

$$\min_w L(X,W,y)$$
Once the model parameters $W$ have been learnt from the model, it is further analyzed to interpret the model. For example, the coefficients obtained from a logistic regression model can be converted into an odds ratio, which is easier to interpret by domain experts who prefer models of simpler forms.[16]

Another useful technique to interpret the model parameters is to impose some sparsity constraints on the model parameters. In that case, the objective function will contain both the original loss function and an additional penalty imposed on the complexity of the parameters. The function is shown in the equation below, where $\lambda(W)$ denotes the complexity of model parameter set $W$. One popular example of such loss function is L1-norm regularization penalty [23], since it can perform feature selection simultaneously with model learning, and that will help reduce model complexity:

$$
\min_W L(X, W, y) + \lambda(W)
$$

Taking prior knowledge into account: Despite that PGHD are usually collected from heterogeneous data sources, the observational data can be interrelated by certain latent factors or well-established medical knowledge. For example, most of the interventions and care workflows are conducted using a few well-established guidelines. Such guidelines can capture the inherent relationships among observational healthcare data including both PGHD and EHR.

In addition, features obtained from observational data may be well structured with semantic relationships among them. For example, drugs, adverse reactions and diagnostic similarity each has clear role in a hierarchical organization based on how specific or generic it is in its mechanism of actions.

These pre-existing relationships are usually curated with the help of multiple domain experts and a standardized protocol.[24] In particular, the interpretability metrics is quantified as knowledge structural similarity, using a distance metric based on the distance of each pair of features in its hierarchy

$$
H_{ij} = \frac{\text{depth}(\text{LCA}(X_i, X_j))}{\max(\text{depth}(X_i), \text{depth}(X_j))}
$$

Here, LCA defines lowest common ancestor of each pair of two features $X_i$ and $X_j$, and depth of $X_i$ defines length of the shortest path from the root of the tree toward $X_i$. Moreover, this distance metric is normalized by the maximum depth of the two features. Finally, this new metric is incorporated in the original penalty structure of the objective function as below:

$$
\min_W L(X, W, y) + \lambda_1(W) - \lambda_2(H)
$$

Note that similar concepts can be generalized when prior relationships exist not only among the features from one type of data, but also features coming from multiple data-sources such as the heterogeneous exogenous determinants in PGHD.

Adapt with Small Data: Interpret from Patient Perspective

Second, in order to adapt interventions on an individual basis, we include an optimal policy learning component that can tailor interventions against incoming streams of “small” data. The goal is to provide interpretable evidence that can help patients and their care teams make decisions that meet patients’ individual needs. In this paper, we introduce components of patient grouping and calibration to evaluate and to inform interpretability-aware analytics.

Patient Grouping: To overcome the barrier of “one-size-fits-all” guidelines to treat all patients as an “average” patient, we apply behavior segmentation methods [25] that can identify sub-cohorts that exhibit distinctive behavioral differences and extract signature behavioral patterns. In the framework, behavioral factors are constructed as a composite of multi-source features for each subject in the cohorts. We illustrate the design of a framework able to generate, analyze and re-rank the risk factors for the behaviorally different segments (as shown in Figure 3; for a more detailed description of the key component of patient grouping, please refer to [25]).
Further, the system can prompt the users for labeling of inputs corresponding to the erroneous variables. This kind of dynamic feedback system will improve the data quality for analysis and improve the prediction accuracy for each person.

Discussion
In this positional paper, we summarize the major dimensions of interpretability and describe the interpretability-aware framework for further adding a patient focus into the care process. The interpretability-aware framework helps foster a continuous learning health care system as pictured in the “All of Us” platform under the Precision Medicine Initiative (PMI).[27] The framework will establish prospective effectiveness based on the basic phenotypes found in mass data and new cases matching some basic phenotypes. This framework, when coupled with the best practice defined for clinical flow to increase patient understanding, is expected to further fuel the patient-centered care model for minimally disruptive medicine.[28] The framework is expected to facilitate the integration between science of data and science of care at the touchpoint. This is especially important for the complex care scenarios wherein standard guidelines and general population-based evidence fall short.

Comparing person-centered effectiveness at touchpoint
Traditionally, comparative effectiveness studies are used to provide evidence to handle “average” patients. Comparative effectiveness studies, if done with a patient focus, can empower patients to better understand and take charge of their decisions. Therefore, in the proposed framework, we further include additional patient grouping and re-calibration steps to reinforce the patient focus.

In retrospect, it can also help identify hypotheses to be verified or falsified. Although classification modeling analysis has become a routine tool in health informatics research, extracting actionable insight from such information remains a major challenge. Formalizing the interpretability metrics and framework such as the correction metrics can help pinpoint the previously unobserved inefficiency of practice and attribute it to variables that matter to patients sub-cohorts and providers, as opposed to those that only add noise.

Putting Big Data and Small Data Together
In terms of the actual implementation, formalizing and scaling up the interpretability-aware framework means solving various practical problems. These include conducting feasibility study of monitoring devices and developing new forms of outcomes.

Take the assessment of stress-behavior relationship as an example. Traditionally, this is done with survey-based ecological momentary assessment (EMA).[29] By coupling EMA with mobile devices, we can repeatedly collect exposure data of psychosocial stressors in ecologically valid settings such as home and work, and in real time. Compared to the survey-based EMA, mobile EMA enables collecting data with the immediate context and substantially reduces recall bias. [30]

In fact, oftentimes, we would not need to develop individual models from scratch, but rather to recalibrate the existing population-based model using user’s own data. The confidence level can be estimated with the sub-cohort identified from the patient grouping step. The recent trends of N-of-1 trials have started to provide evidence on the effectiveness of such approaches for adaptive design.[30,31] Currently in the field, researchers are attempting to apply N-of-1 methods to develop individualized predictive pathways that can be applied to adapt interventions at the touchpoint directly.

The societal approval and ethical issues going forward
It will also require a cultural shift from large, population-based trials to ad-hoc, post-trial analyses that aim to interpret the factors that cause some patients to be responsive. We have to meet such challenges as balancing the economic power of holding the data against the moral maxim of equitable access for citizens to individualized recommendations. Since the data themselves often are public domain there is a moral obligation to make them available free of charge. Since the aggregation of the data requires proprietary technology, there is equal legitimacy to charge market prices for such recommendations.

This compares to the question whether medical advice is a commodity or a merchandise. We have to find answers for patients who find themselves in a Gestalt whose treatment by far exceeds their individual economic reach. We have to find agreement, world-wide—since the origin of data is world-wide—how to handle the detection in passing of alarming conditions: are we entitled to know the name of data source and its identity and to take action? May we, who detect a risk, even be obliged to take action or else be taken accountable for nonfeasance, as physicians would be? Therefore, do we, as informaticians who are engineers in a wide sense, assume the role of physicians and hence inherit the moral standards that physicians have to uphold? Does such an obligation differ between individual risks and societal risks such as epidemics?

Today, we are far from answers. We will, however, demonstrate how principles and maxims from ethics can be used as tools to address these and more questions.[32]

Conclusion
The advent of large-scale PGHD collected from diverse sources poses unique opportunities to harvest insights about patients’ behavior and response to a particular treatment, which can ultimately be used to derive knowledge for making better clinical and self-care decisions. Given the prevalent adoption of EHR and the shift to value-based care, many leading healthcare systems are now evaluating the value of PGHD generated from care processes, which can be either used directly to enhance care processes, or aggregated in big data to derive practice-based evidence.

Traditionally, the generation of clinical evidence relies on RCT and comparative effectiveness studies, which employ costly clinical trial research design and observational data sources such as EHR, claims and administrative data. While these data sources reveal valuable information about treatment effect and healthcare utilization, individual patient data are still needed to identify individually outcome-differential health determinants such as in their social, behavioral, environmental, and psychological factors.

However, the current interpretability of PGHD-driven insights is still questionable when applied to real world applications. In addition, the interpretation of such insights often hinges on experienced healthcare professionals (e.g., care managers). By applying the framework to communicate, it is easier to advocate for post-statistics decision models, which often incur new forms of outcomes and social desirability bias.

This inevitably incorporates humans in the loop during the process of transforming big data to practice-based knowledge and developing such evidence at the touchpoint for individuals.
In this positional paper, we first identify the major dimensions of interpretability. Then, we depict our interpretability-aware framework in which interpretable analytics are enhanced to better incorporate PGHD insights back to the care flow. The aim is two-fold.

First, the proposed framework gives care team tools to address two major challenges: (1) Enable the generation of practice-based evidence from aggregating “big data” from heterogeneous PGHD sources, especially useful for complex care scenarios wherein no clear evidence or guidelines are applicable; (2) Learn to further adapt population health-based recommendation with “small data” from individuals or subcohorts for self-care and experimentation.

Second, the framework aims to make personalized recommendations on what to intervene on at the touchpoint. However, oftentimes the human opinions are subjective and highly depend on their prior expertise and training, which lead to underlying bias and noise factors and decrease the generalizability of the model. Therefore, how to extract best practice and make it scalable throughout organizations and in real world applications is the key for future uptake in practice.

These issues can be mitigated to some extent by taking human knowledge into account in an earlier stage of model development rather than during the model validation step. Therefore, the proposed interpretability-aware framework can help pinpoint more relevant yet explainable risk factors along with their relationships with disease outcome. The bottom line is that these methodological advances should be used to augment, but not to replace the central role of human insights in predicting behavior that can be intervened on.

Using the interpretability aware framework, we can also establish prospective effectiveness of interventions based on more interpretable basic phenotypes found by the patient similarity in mass data. This is important to identify evidence deployable for individuals with uncommon characteristics rather than hiding the apparent noise they contribute as variance and noise.

Abstract

Lorenz plot (LP) method gives a global view of long-time electrocardiogram signals, is an efficient simple visualization tool to analyze heart rate variability and cardiac arrhythmias. 50 records of RR-interval time series with frequent premature complexes exported from 24-hour Holter. Constructed three-dimensional LP (3DLP) with three successive RR intervals as X, Y and Z axis in Cartesian coordinate system for each record, then stereographic projection it along the space diagonal. The radii of dots distinguished eccentric clusters (ECs) points from centric clusters’ with the accuracy of 94±6.0%. The eccentric scatter-dots were separated and identified by the frequency distribution characteristic on azimuth, with the accuracy of 93±11.3% ECs. The APF < -2.8° of CPN EC supported the ventricular extrasystoles diagnosis, with excellent sensitivity (1.0) and specificity (0.92). The transformed coordinates (polar radius and angle) of 3DLP could extract and quantify clusters to diagnose arrhythmia, and might provide additional prognosis information.

Keywords:
Arrhythmia; Electrocardiography; Prognosis

Introduction

Lorenz (Poincaré) plot (LP) is a scatterplot on which each RR-interval (RRI) is plotted against next RRI, and it has been confirmed as a simple visualization tool to analyze heart rate variability (HRV) and cardiac arrhythmias [1]. Esperer reported that the LP method had the potential to significantly improve the accuracy of arrhythmia detection and differentiation [2]. In fact, this method highly depends on the recognition and classification of distinct scatter distribution patterns, i.e. the numbers and the relative positions of the scattered dots gathering regions, which are also known as clusters or attractors [1]. However, there is no efficient method of automatic recognition of LP morphologies, not to mention the method of cluster extraction and quantification [3]. So far, doctors still examine and analyze cases by the eyeball method, which is limited by their subjective experience. On the other hand, investigators might be interested in the number, morphology, position, size or density of clusters, because these may reflect the underlying information of corresponding cardiovascular status and cardiac electrophysiology. Some indices of LP have been extracted from clusters characteristics to evaluate the risks of occurrence of lethal cardiac arrhythmia [4], or predict the probability of onset or termination of paroxysmal arrhythmia [5]. Then again, HRV has become an important method for assessing cardiovascular autonomic regulation. Most quantitative markers may be influenced by noise, ectopic beats, or other rhythm abnormalities, especially in frequent condition [6]. But, non-stationarities are important both as confounders and information conveyors. We assumed the quantification indices of clusters may supply additional information of predicting the occurrences and outcomes of arrhythmias and other cardiovascular diseases.

Methods

3DLP construction and clusters extraction

The RRIs series were described as a time series vector \([x_1, x_2, \ldots, x_n]^T\). The 3DLP was constructed of the plot of \(x_i\) on the x-axis, \(x_{i+1}\) on the y-axis and \(x_{i+1}\) on the z-axis in three-dimensional Cartesian coordinate system, that was, the \((x_{i-1}, x_{i}, x_{i+1})\). Stereographic projection (SGP) of 3DLP along the space diagonal, there were one central cluster (CC) and four or more eccentric clusters (ECs) (see Figure 1.a and b). The clusters or points were located by polar coordinate system’s radial \((r_{\alpha})\) and angular \((\theta)\) coordinates while the pole was set at \((45^\circ, 35.3^\circ)\). Divided the polar angular into 361 areas from \(-\pi\) to \(\pi\) then counted the eccentric points of each area. The histogram of each EC presented normal distribution characteristic, with a distinct peak frequency in the middle (\(A_{PP}\)) and absolutely low frequency clockwise (\(A_{DP}\)) and counterclockwise (\(A_{LP}\)) borders (Figure 2). A searching procedure was designed to acquire such azimuths of each wave until the \(A_{PP}\) was small enough.

Clusters’ extractions were automatic segmentations of 3DLP based upon homogeneously statistical properties of each coordinate element. The \(r_{\alpha}\) were used to distinguish CC points from ECs’, and the azimuths (\(A_{PP}\) etc.) were used to separate and identify ECs. The spherical radius \((r_{\alpha})\) of centric cluster permit to depart each part of it, if exist.

Professional software was developed to construct and extract clusters by our study group based on Matlab R2013. The development and running platform was Windows 7 operating system shipped on a personal computer, CPU 3.3 GHz, memory 2.0 GB.
Data source

The 50 cases of 24-hour Holter recordings obtained from our laboratory of the People’s Hospital of Huangshan, which were artifact-free recording time of at least 22 hours and only frequent (>1000 times) unifocal (atrial or ventricular) premature complexes without other arrhythmias. The apparatus was DMS 300-3 Holter recorder and analyzer system, 128 Hz sample frequency. All records had been verified carefully by experienced cardiologist. Redefined the RRI annotations that: a normal-normal RRI as N, a pre-ectopic coupling interval as C, and a post-ectopic pause interval as P, the intervals preceded or followed an artifact, infrequent focal or interpolated extrasystole were marked as Z. The 3D dot-marker was composed of its successive three RRIs annotations (such as NPC) and used as standard classification of dots.

Statistical analysis

Quantitative results were indicated as mean values with pertinent standard deviations, or as percentages. The receiver operating characteristic (ROC) method was used on each record to explore the optimal threshold values, with the areas under the curves (AUC) for each feature represented by the ROC area.

Results

Frequent atrial or ventricular premature complexes records had 25 apiece. In each record, the numbers of RRIs were more than 80,000. The amount of P labelled RRIs was more than 1000; the total of Z labels was less than 100. Only clusters with the amounts of points more than 100 were accepted to analyze. 3DLP displayed multi-distribution subgraphs solid pattern emitted from the origin, more or less (Fig.1.a). Each cluster had unique color after colorized dots of each marker with a kind of color. That means a cluster was composed of points which had same pathological mechanism. By using the 3D dot-markers, it’s easy to distinguish CCs from ECs for the former was composed of three exactly same RRI annotations, but the latter otherwise. It’s also efficient to differentiate each EC.

The pathological mechanism of ECs was a regular ratio of sinus and ectopic beat occurrence. Each mark’s EC had a relatively consistent A_PF between different patients and between different types of arrhythmias. They could be NNC, NCP, CPN and PNN when single premature beat occurred (A_PF located about at -91±10.7º, 135±4.9º, -2±7.8º and -151±2.6º on SGP, respectively), CPC and PCP happened on bigeminy (about at -30±12.0º and 159±5.4º, respectively), PNC arose in trigeminy (about at -148±7.3º), PCC appeared in true trigeminy condition (about at -142±6.1º and 90±14.9º, respectively). The CC common was NNN cluster sourced from normal sinus rhythm, occasionally, accompanied with CCC if existed any salvo premature beats.

All 50 records, the mean numbers of 3D points were 94774±11756. The ROC method found that the mean cutoff value for r2d was 4.7±2.83º led the mean of sensitivities 0.95±0.07 and specificities 0.91±0.13 to distinguish both with AUC 0.95±0.09. Once adopted 4.7º as the cutoff value, the mean numbers of correct classified points were 89651±13813, accuracy rate 94±6.0%. Besides, we deduced that the minimal r2d value of the lowest frequency of the histogram of r2d could be used to identify sinus arrhythmia and atrial fibrillation, because the former was less often than 10º and the latter usually greater than 17º.

The mean thresholds of r2d from 9 records which met the statistical requirement was 1166±189.3 ms lead the mean of sensitivities 0.87±0.10 and specificities 0.92±0.09 to separate the CCC from NNN cluster with AUC 0.93±0.08. The numbers of CC points were 4572±29359, once adopted 1166 as the cutoff value, correct classified 42628±28543 (89.8±7.51%).

Adjacent clusters had distinct A_PF values (the difference was more than 10º except PNN, PCC and NCC). It’s possible to recognize the ECs by the A_PF values generated from the extraction procedure when RRIs annotations were not available, i.e., calculate the absolute values of the acquired A_PF minus the experienced A_PF as (described above), if someone (let NCP) was the minimum one and the difference was less 10º, then the 4th cluster was that labelled clusters (i.e. NCP, and so on). There were 6±2.6 ECs in the 50 cases; the numbers of correct recognition were 5±1.6, accuracy rate 93±13.3%. The numbers of ECs points were 27452±27790, correct classified 23822±23930 (89±12.6%).

The A_PF is a powerful index of differential diagnosis of atrial and ventricular extrasystoles. The ROC method found that the A_PF of CPN, PNC and NCP classified ventricular well from atrial, yielded AUC 0.98, 0.93 and 0.91 (all P<0.01), respectively. The A_PF < -2.8º of CPN cluster supported the ventricular extrasystoles diagnosis, with excellent sensitivity and specificity of 1.0 and 0.92, respectively. The result showed that 96% (48 of 50) of cases classified correctly.

Discussion

Extraction and quantification clusters of 3DLP

The quantification indices of LP clusters may supply additional information of predicting the occurrences and outcomes of arrhythmias and other cardiovascular diseases [2]. It’s necessary to extract each cluster first. The dot-markers composed of RRI-annotations are helpful to do so, and make an opportunity to study the pathological mechanism of clusters. But they are not always available in clinical practice. It’s necessary to develop an efficient method to achieve the goals.

In this paper we constructed a kind of 3DLP, in which, 3D scatter point was plotted with three successive RRIs as X, Y and Z axis in Cartesian coordinate system [1]. The clusters’ space contours are more distinct for less overlap each other. The polar radius and angle of stereographic projection 3DLP along the space diagonal allow separation and recognition centric cluster. But it’s still uncertain what additional cardiovascular pathology or physiology information could be provided by such parameters [1].
Relationships between 3DLP and 2D LPs

The morphologies of 3DLP viewed on XY or YZ plane are identical to the first-order of LP in every detail (Figure 3.a). The stereographic projection of 3DLP and the second-order of LP are much more alike than different (Figure 3.b). They are similar in amount and pattern of clusters, but have minor difference in radius, azimuth and overlap portions. Once we add a fourth dimension, the time dimension, which may be hidden, to 3DLP, it’s easy to realize the retrograde technique, i.e., inspect any points on tachograms, even the ECG waves of the corresponding RRIs, and vice versa, since both of them have a unique time dimension. Different clusters of 3DLP belong to different layers on tachograms when selected Y coordinates of 3D points correspond to y-axis of tachograms (Figure 4). Since the strong relationship exists among those different LPs, it indicates that we can apply the extracted clusters to conventional 2D LPs, and the majority of 2D LPs achievements could be utilized to 3DLP as well.

Limitations

We focused on extraction clusters of frequent arrhythmias in 3DLPs, which implied that arrhythmic episodes with a low incidence were ignored. There were few clusters still impossible to be extracted by this method, for example, if the PNN, PCC and NCC coexist. Atrial and ventricular arrhythmias coexistence in a 24-hour Holter recording was common; this study provided no methods to separate each other due partly to LPs lose QRS morphological information. This study didn’t inspect all types of arrhythmias for insufficient data, nevertheless the proposed methodology provided the basic principles of how clusters are assessed.

Conclusion

This study provided two methods to extract clusters of 3DLP. The first one is gathering same markers’ dots as a cluster, where the marker is composed of annotations of successive 3 RRIs which constructed this dot. This method requires high quality of ECG recordings and the recordings has been analyzed accurately. The second one is separating dots into different clusters by its frequency distribution characteristic on space coordinates. This method is applicable on raw RRIs data but may generate some deviation.

3DLP has significant advantage of extraction and recognition clusters for sufficiently less overlaps than 2D LPs. It’s also benefited from the strong relationships with multiple 2D LPs.

Abstract

Web 2.0 has become a leading health communication platform and will continue to attract young users; therefore, the objective of this study was to understand the impact of Web 2.0 on health information seeking behavior among university students in Bangladesh. A random sample of adults (n = 199, mean 23.75 years, SD 2.87) participated in a cross-sectional, a survey that included the eHealth literacy scale (eHEALS) assessed use of Web 2.0 for health information. Collected data were analyzed using a descriptive statistical method and t-tests. Finally logistic regression analyses were conducted to determine associations between sociodemographic, social determinants, and use of Web 2.0 for seeking and sharing health information. Almost 74% of older Web 2.0 users (147/199, 73.9%) reported using popular Web 2.0 websites, such as Facebook and Twitter, to find and share health information. Current study support that current Web-based health information seeking and sharing behaviors influence health-related decision making.

Keywords:
Health Literacy; Social Media; Cross-Sectional Studies

Introduction

Nowadays, the Internet is a very common tools to seek information about healthcare and health conditions [1]. A study has confirmed that 83.4% of the frequent internet users age between twenty years to forty years, shows 72% of them are engaged in social networking days and nights [2]. As a large amount of health information is available in web 2.0; so it can be used to educate and empower people. The concept of eHealth literacy which refers to the ability to read, understand and communicate about health information to make the people to take proper health decision [3].

Consumer-directed eHealth requires the ability to seek out, find, evaluate and appraise, integrate, and apply what is gained in electronic environments toward solving a health problem, or eHealth literacy [4]. This composite skill requires that people are able to work with technology, critically think about issues of media and science, and navigate through a vast array of information tools and sources to acquire the information necessary to make decisions [3]. According to Norman and Skinner [5], eHealth literacy is ability to navigate the internet for health information. Thus, eHealth literacy comprise of computer literacy, scientific literacy, health literacy, traditional literacy, media literacy, and information literacy [6]. Norman and Skinner [7] created the eHealth Literacy Scale (eHEALS) to measure individuals’ perceptions of their own digital health literacy skills [8].

Although many studies have used eHEALS scale to determine eHealth literacy despite of lack of evidence [9-13]. Asian countries like Japan and Taiwan researcher used this eHEALS scale for predicting eHealth literacy. But there is no research in Southeast Asian countries using eHEALS scale to determine eHealth literacy. In this study, we construct validity of eHEALS was analyzed among the university students who use web 2.0.

Methods

Study population

A cross-sectional study was conducted in four university (Dhaka Dental College, American International University Bangladesh, Manarat University Bangladesh, and Stamford University Bangladesh). Participants were eligible if they were over 17 and less than 35 years old, capable of reading, writing English, and were willing to sign a consent form and able to complete questionnaire. A total of 199 participants were enrolled 4 investigators from November 2015 to March 2016. All of the 199 participants in this study were included according to gender, age, marital status, computer competency, and pattern of internet use.

Measurement

Computer knowledge and Internet use

Participant were asked about their computer knowledge and amount of internet use. In the past 12 months have they use popular social media and shared any information regarding health. It was not restriction to use desktop or laptop computer, cell phone, mobile handheld device like an e-reader or tablet.

eHealth literacy

In our study, we measured eHealth literacy by using eHealth literacy scale (eHEALS). It is introduced by Norman which is used determines consumers’ combined knowledge, confidence, and perceived skills finding, evaluating, and applying electronic health information to health problems. eHEALS consists of 8-items scored on a 5-point Likert scale ranging from strongly disagree to strongly agree. The scores range from 8 to 40 with higher scores indicating higher eHealth literacy.
from 1 (strongly disagree) to 5 (strongly agree). Higher scores on the eHEALS indicates higher eHealth literacy (total score range=5-40). The internal consistency of the data collected using the eHEALS in this study was high (Cronbach alpha=.740), and comparable to reliability estimates reported in previous studies.

Use of Web 2.0 for Health Information

We asked participants, “In last 12 months, have you used the Internet for any of the following reasons to locate or share health information?” Respondents could select all reasons for using the Internet:

1. Participated in a Web-based-support group,
2. Used a social networking site like Facebook/Twitter/LinkedIn,
3. Wrote in a Web-based diary or blog.

Sociodemographic and Social Determinant Variables

Gender (male or female), age (in years), education (higher secondary school/H.S.C, college graduate, post-graduate), and marital status (married, unmarried, widow and unknown) were all assessed. Perceived health status was also measured using the following scale: (1) poor, (2) fair, (3) good, (4) very good, and (5) excellent.

Statistical Analysis

In our study, we used SPSS version 23.0 to compute frequency and descriptive statistics to analyses sociodemographic and social determinant characteristics, frequency statistics for each eHEALS item, and the number of respondents reporting use of Web 2.0 for health information. We also conducted a multiple linear regression to determine whether use of internet and computer knowledge, sociodemographic variables (sex, age, education, marital status), and perceived health status as a determinant predicted overall eHEALS scores. Finally, a binominal logistic regression was conducted to determine whether these predictor variables were associated with the use/non-use of Web 2.0 for health information. Analyses were considered statistically significant at the P<.05 alpha level (two-tailed).

Results

Participant characteristics

Our study shows that participants age ranged from 17 to 35 years (mean 23.75, SD= 2.87). Male participant had 133 (66.8%) and female had 66 (33.2%). Among participant unmarried was highest number 138 (69.3%), 48 (24.1) were married, 1 (0.5) was widow and 12 (6%) did not answer this question. Over 72% of participant reported completing Bachelor degree and almost a quarter 23.1 (%(46/199) completed Master’s degree. A little over one quarter (27.6%) participants had very good health and 30.7% (61/199) participants had good health status. Table 1: shows the characteristics of study participants included this study (n=199).

Computer competency and internet use

A little over half of the participants were competent in computer 53.3% (106/199), 31.7% (63/199) of despondences were just beginner in computer and about one six percent 15.1% (30/199) despondences were above competent. In the case of internet use, 82.9% (165/199) of participants use internet daily, 11.6% (23/199) use internet once a week.

Reliability and validity

In our study, total scale of eHEALS ranged from 13 to 40 (means 27.46, SD= 4.99). Table 3 illustrates the response frequencies for each eHEALS items. The internal consistency of the eHEALS was alpha=0.74. The variance of the scale was 50.7 percent and all items loaded high on this component,
ranging from .423 to .642. Table 3 shows the correlation the scores on the eHEALS and the variable measured in this study.

**Association between Web 2 for health information and eHealth literacy**

In the case of social media use, the respondents reported the difference in the total eHEALS scores among popular social media such as Facebook, twitter, etc. users (means 28.01, SD= 4.95) and non-users (means 25.98, SD= 4.79). Other response in this question included the difference in the total eHEALS scores among the web support group users (means 27.75, SD= 4.28) and non-users (means 27.24, SD= 5.398). This difference is also observed in the case of blogs, the difference in the total eHEALS scores among blog users (means 27.83, SD= 5.95) and non-users (means 27.42, SD= 4.93). Taken together, these results suggest that there is an association between Web 2 for health information and eHealth literacy.

**Predictors of Web 2 use for health information**

Binominal logistic regression analysis were used to analyze the relationship between web 2.0 use and eHealth literacy. Table 4 provides the summary statistic for predicting use of web 2 for the health information.

**Discussion**

The present study was designed to determine the effect of internet on health literacy among the university students in Bangladesh. In this study sociodemographic variable such as health status and social determinant (e.g. marital status, income etc.) were not significant predictors of eHealth literacy among the university students in Bangladesh. However, gender appeared significant effect especially female significantly effects the use of internet on health information. This finding is contrary to previous study which has suggested that education level, advanced age, and the extent to which electronic devices were used did appear to affect eHealth literacy. Also, they found the level of education, electronic device use influenced the use of internet for health-related information [14]. Furthermore, this present study found that the majority of students used the Internet to find health information, and believed the Internet was useful for helping to make health decisions.

E-Health literacy was found to be influenced by age, education, and marital status, computer knowledge used to search for health information in this study. Participants having higher level of education has been associated with higher amount of internet use for searching health information. Although, Powel et al. [15] studies mentioned education has been associated with more frequent use of the Internet for health information. This view is also supported by a group of researchers from Israel [12]. Besides, unmarried participant’s searching frequency were higher than married participants. In addition, computer competency had great influence in

*P<.05 two-tailed; *Reference category: Not answer; *Reference category: Higher secondary school certificate; *Reference category: Above competent; *Reference category: Once a month
searching health information in internet and it shifted from beginners to competent. Several studies mentioned that demographics, educational background, and technology use uniquely influences health literacy [16-18] and eHealth literacy [4; 19; 20] in the general population.

As Bangladesh is a developing country so there has been some concern that those at lower socio-economic levels do not have equal access to Internet health resources. It is clearly understandable that access to computers are limited, literacy abilities are insufficient, and always lacking of basic computer skills. However, it is true that university students are still the largest percentage of Internet health information seekers and it also exponentially increasing to the other segments of society, obviously they are likely to search for health information. As significant number of university student are using Internet for seeking health resources but how they look for and find high-quality information on the Web still not clear.

While it is important to use the Internet to seek out general health information, majority of adult does not feel interest to discuss their own health problems or obtain personalized medical advice over the Internet. Most of cases they are reluctance to using interactive Internet applications for health communication purposes. It would be more valuable if they seek and share their personal health information other than just usual interaction. It could be the result of contextual Web security issues affecting confidentiality. The issue of trust when using the Internet to seek and share medical information is an important one to consider, especially with the emergence of peer-to-peer or horizontal health communication among university students. More research should be done to discover what particular sources of Web-based health information college students are consulting and which cause uneasy feelings originating from potential threats to data security and privacy.

There are some limitation in our study. Firstly, we only focus young generation who are studying different university; we did not include participants who were not studied in institution. Secondly, we only conducted survey one district, it does not present whole country situation. There may be a need for a more comprehensive survey instrument that assesses health information seeking and sharing using all types of Internet applications. Finally, the cross-sectional research design limits the researchers from establishing causation when considering the interrelationships between sociodemographic variables, social determinants, and health communication outcomes.

Conclusion

Although university students are highly connected to, and feel comfortable with, using the Internet to find health information but it is not still satisfactory. This study has shown that eHealth literacy enhancing program is needed among university students. It is important those who are in the medical and health professions, need customized eHealth literacy training for finding, interpreting, and evaluating health- and medical-related information available on the Internet.

Comparing Cancer Information Needs for Consumers in the US and China

Zongcheng Ji a, Yaoyun Zhang a, Jun Xu a, Xiaoling Chen a, Yonghui Wu a, Hua Xu a

a School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, USA

Abstract

Due to the differences in environments and cultures, consumers seeking cancer information in various regions of the world may have diverse needs. This study compares the cancer information needs for consumers in the US and China. Specifically, we first collected 1,000 cancer-related questions from Yahoo! Answers and Baidu Zhidao, respectively. Then, we developed a taxonomy of health information needs and manually classified the questions using the taxonomy. Finally, we analyzed the characteristics of information needs from consumers in both countries and summarized the differences between them. Our study demonstrated that although there are some common needs between consumers in the US and China, there are several significant differences between the two countries: the Chinese consumers are more likely to seek diagnosis and treatment online, while the US consumers prefer to seek common medical knowledge online.

Keywords:
Cancer; Information Needs; Taxonomy; Consumer Health Informatics

Introduction

Cancer is one of the leading causes of death worldwide. Tremendous efforts from the government, health providers, and pharmaceutical companies have been devoted to developing effective cancer therapies. With the initiative of precision medicine, a recent trend in cancer treatment is to provide personalized cancer therapy [1; 2], in which the proactive engagement from patients regarding treatment preference and healthcare data sharing plays a critical role. Therefore, multiple healthcare organizations (e.g., Mayo Clinic 1) and government institutes (e.g., National Cancer Institute of US 2) provide comprehensive online cancer knowledge services and have developed patient portals to answer healthcare questions and collect feedbacks, for better patient education and engagement in personalized cancer therapy.

Meanwhile, consumers (e.g., patients, family members, friends) seeking cancer information all over the world are also eager to know different cancer-related information, ranging from common knowledge about the causes, symptoms, and treatments to the most suitable healthcare providers and emerging new treatment options in the era of precision medicine. Moreover, people in different regions are attempting to find cancer knowledge and therapies worldwide to leverage better healthcare resources. Therefore, it is necessary to build automated informatics tools such as search engine or question answering systems that can integrate the rich resources and provide more efficient and effective cancer knowledge services for consumers. One essential step toward this goal is to first understand the specific cancer information needs of consumers, in order to provide the most helpful information.

Fortunately, such information needs are expressed in various social communities, such as online question answering communities where people can ask their questions and answer others’ questions (e.g., Yahoo! Answers 3 in the US and Baidu Zhidao 4 in China). As time passed, these websites have accumulated a large amount of cancer-related questions and answers, which provide us invaluable data resources for understanding consumer health information needs. However, people from different regions with different cancer distributions, therapy development and cultures may have different information needs [3; 4]. For example, our preliminary study reveals that consumers in the US prefer to know the causes or risk factors of cancers, while consumers in China pay more attention to seek possible treatments online. Identifying the differences in information needs among consumers in different regions will facilitate the building of more advanced automated cancer knowledge services (e.g, search engines / question answering systems) which can provide knowledge / answers according to consumer-centered information needs. Furthermore, being aware of the different information needs required by the consumers will also facilitate cross-region collaborations for cancer diagnosis and treatment, such as the rapidly emerging international telemedicine.

There are several studies [5-11] that have analyzed cancer-related questions to understand consumer information needs. These studies mainly focused on very specific topics, including the information needs of post-treatment cancer patients [7; 9], patients in self-characterized illness phase [8], breast cancer patients [10], rare cancer patients [6], melanoma patients [11] and cancer patients’ questions about pain [5]. However, no comprehensive study of consumer information needs of cancers has been conducted. Furthermore, the differences in information needs among consumers in different regions of the world have not been previously investigated. This study compares the cancer information needs for consumers in different regions. As a starting point, we set the comparison between the US and China, because

1 http://www.mayoclinic.org/
2 https://www.cancer.gov/
3 https://answers.yahoo.com/
4 https://zhidao.baidu.com/
both countries have large scales of patients with different cancer distributions and cultures [3; 4]. Specifically, we first collected 1,000 cancer-related questions from Yahoo! Answers and Baidu Zhidao, respectively. Then, we developed a taxonomy of health information needs and manually classified the questions using the taxonomy. Finally, we analyzed the characteristics of information needs from consumers in both countries and summarized the differences between them. As far as we know, this is the first study to compare cancer information needs for consumers in the US and China. Our study will greatly benefit the development of automated cancer knowledge services for consumers as well as the cross-region collaboration for cancer therapy.

Methods

Datasets
We collected cancer-related questions from Yahoo! Answers and Baidu Zhidao, which represent the most popular online question answering communities in the US and China, respectively [12-16]. More specifically, we collected questions under the category of “Health / Diseases & Conditions / Cancer” from Yahoo! Answers and “医疗健康 / 肿瘤科 (Health Care / Oncology)” from Baidu Zhidao. To facilitate analysis, we took the subject field as the question without considering the description field, which contains the detailed description. Finally, we collected 9,043 and 166,469 questions in English and Chinese, respectively.

We randomly sampled 1,000 questions from each dataset to conduct the comparative study. As all the questions are user generated, some questions are not clearly described (e.g., Brain tumor?) or even not related to the cancer topic. We discarded these questions and randomly sampled new ones to keep the sample size at 1,000 for each dataset.

Taxonomy

To characterize consumer health information needs, a taxonomy is needed to classify the consumers’ questions. The Taxonomy of Generic Clinical Questions (TGCQ) [17] is one of the most popular taxonomies for classifying health-related questions. Several studies [17; 18] show that TGCQ is useful for analyzing physicians’ and case managers’ information needs, but is not suitable for consumers’ questions due to the difference in the information needs between the physicians and the consumers [19]. We are aware of one recent study [19] that developed a taxonomy mainly based on TGCQ for analyzing consumer health information needs on hypertension related questions. However, this taxonomy is incomplete or somewhat confusing for our case. For example, there is no category for the questions regarding seeking second opinions, finding similar experiences and asking financial support, where these three categories take up 11.7% of the English questions in our study. Furthermore, we also created a new category named Common Knowledge, which covers the definition, prevalence, etiology, prognosis or information resources of some conditions, etc. Finally, based on TGCQ and the taxonomy developed in the work of [19], we developed our new taxonomy, which consists of two levels of categories. The first level contains 10 main categories and the second level contains 28 subcategories. The detailed definitions for the 10 main categories are shown in Table 1 and the 28 subcategories can be found in Table 2.

Annotation

We manually reviewed 100 questions from both the two datasets to develop an annotation guideline. Table 3 shows several examples from the annotation guideline. For instance, the question “Why does cancer treatment work for some and not others??” can be classified into the main category Treatment, but cannot fall into any other subcategories of Treatment (i.e., Drug Therapy, Surgery, Other Treatments and Treatment Seeking). Thus, we classify this question as Treatment→Other. Two annotators who are fluent in both English and Chinese manually classified the 2,000 questions (1,000 in English and 1,000 in Chinese) with the taxonomy we developed. The disagreements in the annotations were solved through group discussion including the two annotators.

Statistical Analysis

Cohen’s kappa [20] was used to calculate inter-annotator agreement scores for the first level categories and the second level categories. We examined the frequency distribution of cancer-related questions among the first level categories and the second level categories for both the English dataset and the Chinese dataset. We also compared the frequency distribution across the English questions and the Chinese questions to identify the differences.

Results and Discussion

Taxonomy reliability

The two annotators manually annotated the 1,000 cancer-related questions from Yahoo! Answers (US) and 1,000 cancer-related questions from Baidu Zhidao (China) using the developed taxonomy. Table 2 shows the frequency distribution over the two-level categories for the two datasets. The kappa measurement implemented in Stata was used to calculate the inter-annotator agreement between the two annotators.

</table>

For the first level categories, the two annotators achieved a Kappa score of 0.9105 and 0.9502 for the English questions and the Chinese questions, respectively. For the second level categories, the two annotators achieved a Kappa score of 0.8976 and 0.8798 for the English questions and Chinese questions, respectively. The good kappa scores indicated that the two annotators achieved high agreement on both of the two-level categories.

**Frequency distribution of cancer information needs in US**

Among the 1,000 English questions from Yahoo! Answers, the most frequent main category is Common Knowledge (42.3%), with the most frequent subcategory being Etiology, indicating that consumers in the US were more concerned with the cause or risk factors of diseases. The second most frequent main category is Treatment (21.2%), where the most frequent...
Frequency distribution of cancer information needs in China

Among the 1,000 Chinese questions from Baidu Zhidao, the most frequent main category is Treatment (35.2%), where the most frequent subcategory is Treatment Seeking, indicating that consumers in China care more about seeking possible treatments online. The second most frequent main category is Diagnosis (24.7%), where the most frequent subcategory is Condition. The third most frequent main category is Common Knowledge (24.4%), where the most frequent subcategory is Etiology. The frequency distribution for other main categories are 7.1% for Healthy Lifestyle, 4.8% for Healthcare Provider Choosing and 2% for Prevention. There are very few questions about requesting second opinions, finding similar experiences and asking for help with financial support.

Comparisons of cancer information needs between China and US

Figure 1 and Figure 2 shows the comparisons of frequency distributions over the 10 main categories and the 28 subcategories for the two datasets, respectively. From the two figures, we can find that the most frequent main categories for both datasets are Common Knowledge, Diagnosis and Treatment, which covers 77.4% and 84.3% of the questions in the two datasets, respectively. This indicates that consumers in the US and China have the similar concerns even with different healthcare systems and cultures.

Figure 2 – Comparisons of frequency distributions over the 28 subcategories for the questions from the US and China

Acceptance and Use of eHealth/mHealth Applications for Self-Management Among Cancer Survivors

Yun Jianga, Brady T. Westb, Debra L. Bartonb, Marcelline R. Harrisa

aSchool of Nursing, University of Michigan, Ann Arbor, Michigan, USA
bInstitute for Social Research, University of Michigan, Ann Arbor, Michigan, USA

Abstract

Cancer survivors’ acceptance and use of eHealth/mHealth applications for self-management can be unique and are not fully understood. We used data from the Health Information National Trends Survey 4 Cycle 4 to examine cancer survivors’ acceptance and use of eHealth/mHealth applications for key self-management processes, and conducted logistic regression and Rao-Scott design-adjusted Chi-square tests to assess bivariate associations between potential predictors and actual use. Potential factors were selected based on the Individual and Family Self-Management Theory. High acceptance of eHealth applications was identified, and adoption of mHealth was relatively low. Younger, higher educated, married, employed, and higher income survivors tended to use eHealth/mHealth applications for self-management. Survivors who were newly diagnosed or still on treatment were more likely to look for cancer information online or communicate with health providers electronically. BMI and rural residency were associated with use of mHealth apps to achieve a health-related goal and treatment decision-making.

Keywords:
Mobile Applications; Self-Management; Neoplasms

Introduction

Advances in cancer diagnosis and treatment have led to longer survival. More than 15 million Americans diagnosed with cancer were alive by January 1, 2016 [1]. Similar to persons with other chronic conditions, cancer survivors are expected to perform self-management starting at the point of diagnosis, in order to achieve their long-term care goals. However, cancer survivors may lack the confidence or skills to perform self-management of symptoms, take medications, implement lifestyle changes, and deal with other consequences of cancer [2]. Many factors can affect their long-term engagement in self-management, such as individual, condition-specific, family, and environmental factors [3]. Conceptual descriptions of self-management have identified five core self-management processes, including problem solving, decision-making, resource utilization, partnerships with healthcare providers, and taking action [4]. To accomplish those processes, cancer survivors will need support from family and friends, healthcare professionals, communities, health systems, and possibly information and communication technologies [5]. The development of Web- and mobile-based health-related applications is increasing, with the goal of facilitating health behavior changes and support of patients in chronic disease self-management [6, 7], including limited applications in cancer self-management [8, 9]. Some applications have integrated behavior change techniques, such as goal setting, self-monitoring, and decision support feedback, potentially making them convenient and powerful tools to support self-management behaviors and improve health outcomes [10]. However, a significant body of scientific evidence has not been established for the effectiveness of current web- and mobile-based self-management interventions [6-8, 11]. It has been suggested that the eHealth/mHealth system development process should fully assess user perceptions and address their unique needs [9]. More generally, the feasibility and acceptability of using web- or mobile-based technology for health self-monitoring needs additional investigation [7].

The purpose of this study was to understand cancer survivors’ perceptions and actual use of Internet and mobile technology to support their cancer self-management needs, with a specific focus on four self-management processes: (1) resource utilization, operationalized as cancer information seeking and access to personal health information; (2) treatment decision making; (3) taking action, operationalized as achieving health-related goals; and (4) partnership with healthcare providers, operationalized as exchanging medical information with health care professionals. Further, factors associated with survivors’ actual use of technology for self-management processes were explored.

Methods

Data used in the study were from the National Cancer Institute’s Health Information National Trends Survey 4 (HINTS 4) Cycle 4, which is the first cycle of HINTS that included questions about adoption of mHealth applications [12]. The HINTS targets American adults aged 18 and older, to assess their knowledge of, attitudes toward, and use of cancer- and health-related information [12]. Cycle 4 used a single-mode mail survey, with a two-stage sample design, including a stratified sample of addresses and a selected adult within each sampled household [12]. The data were collected from 3,677 respondents from August to November 2014, with an overall 34.04% response rate [12]. This study focused on the subpopulation of individuals who have ever been diagnosed with cancer, of which there were 542 respondents in HINTS 4 Cycle 4.

Guided by the Individual and Family Self-Management Theory [3], potential predictive factors were categorized as contextual factors and self-management process factors, including socio-demographic characteristics, clinical characteristics (diagnosis and treatment), health status, psychological distress, knowledge and beliefs (self-efficacy, belief in cancer cause), self-regulation skills and abilities (preference of shared decision making), and social facilitation (social support and regular exercise pressure from others)
(Table 1). As shown in Table 2, outcome measures included cancer survivors’ acceptance of the Internet and mHealth apps, and actual use of the Internet and mHealth apps for health self-management processes.

All statistical analyses considered the complex design of the HINTS 4 sample. The final sample weight variable was used to calculate population estimates, and 50 replicate weights were used to calculate accurate standard errors of the weighted estimates using the jackknife replication method [12]. Specifically, descriptive statistics were used to summarize the cancer survivor population characteristics and their acceptance and use of eHealth/mHealth technologies for self-management. Bivariate logistic regression analyses were used to assess relationships between each potential factor and cancer survivors’ seeking cancer information via the Internet, access to online patient portals (PHR), and exchanging medical information with a health care professional through various technologies. Regression coefficients were estimated by pseudo-maximum likelihood estimation methods and odds ratios were reported. Rao-Scott design-adjusted Chi-square and F-tests were used for cross-tabulations to examine associations between each potential factor and cancer survivors’ using mHealth apps for achieving a health-related goal, and for making a treatment decision. All statistical analyses were conducted using Stata (version 14, StataCorp LP, College Station, TX). The level of significance was 0.05.

Results

Most adult cancer survivors in the US were more than 65 years old, female, non-hispanic white, at least high school educated, currently married, unemployed, and reported their household income to be over $50,000. More than half of survivors were overweight or obese, had the diagnosis of cancer more than 5 years ago, and had at least 2 other chronic conditions in addition to cancer. The majority felt good general health and no distress, were very confident in taking care of their own health, and had support from their friends or family (Table 1).

Regarding cancer survivors’ acceptance of eHealth/mHealth applications for self-management, most survivors had access to the Internet (73.9%), trusted online cancer information (68.9%), and considered it very important to be able to access their own health information electronically (67.7%). However, more than one-third of survivors did not have a smartphone or tablet (40.4%), and only 23.4% of survivors had the mHealth apps. In addition, less than half of survivors (44.7%) reported that they were somehow or very interested in exchanging medical information with a health care professional electronically (Table 2).

In the past 12 months, a limited number of cancer survivors usually used the Internet to look for cancer information for themselves (31.8%), accessed their personal health information online (29.4%), and had exchanged medical information with a health care professional through email, text message, mobile apps, video conference or social media (29.8%). There were even fewer survivors using mHealth apps to help achieve a health-related goal (13.0%) or make a decision about how to treat an illness or condition (7.6%) (Table 2).

Cancer survivors who were diagnosed less than 1 year ago had not found to be associated with survivors’ access to PHR. Other factors, such as education, marital status, employment, and income, indicated that age, education, marital status, employment status, income, cancer type, years of diagnosis, time of last treatment, and belief that everything causes cancer were not found to be associated with either access to PHR or exchanging medical information electronically (Table 3).

As shown in Table 3, bivariate logistic regression results indicated that age, education, marital status, employment status, income, cancer type, years of diagnosis, time of last treatment, and belief that everything causes cancer significantly predicted survivors’ seeking cancer information online. Specifically, the odds of seeking online cancer information were 4.02 and 2.77 times higher among survivors aged 35-49 and 50-64 years than those aged 65 years and older. The odds were also higher among higher educated, married, employed, and higher income cancer survivors. Breast cancer survivors have 2.08 times higher odds of seeking cancer information online than other cancer survivors, while the odds for prostate cancer survivors were 65% lower than other cancer survivors. Cancer survivors who were recently diagnosed or still on treatment had higher odds of seeking online information than those who had been diagnosed for more than 2 years or had their last treatment more than 1 years ago. Other factors, such as gender, race, BMI, number of comorbidities, health status, self-efficacy, and social support, were not found to be significant correlates.

Access to PHR and exchanging medical information with HCP electronically had similar associations with the socio-demographic predictors, that is, married, employed, and higher income survivors had higher odds of using eHealth applications for self-management. However, education was not found to be associated with survivors’ access to PHR. Cancer survivors who were diagnosed less than 1 year ago had higher odds of using technology for exchanging medical information with HCP. Other cancer-related characteristics, such as cancer type and years of diagnosis, and beliefs that everything causes cancer were not found to be associated with either access to PHR or exchanging medical information electronically (Table 3).
management. In addition, obese survivors were more likely to use mHealth apps to help achieve a health-related goal, such as losing weight or increasing physical activity, while survivors living in rural areas were more likely to use mHealth to help make treatment decisions.

Discussion

This study described cancer survivors’ acceptance and actual use of web- and mobile-based health applications for self-management, and explored potential factors associated with their actual use. The dataset was from a national mail survey with a complex sample design. Findings of this study are expected to be generalized to the US adult cancer survivor population.

Findings of the study indicated high acceptance of eHealth applications and a relatively low adoption of mHealth apps for self-management. It is believed that the eHealth/mHealth system can provide convenient platforms for patients to engage in self-management, especially in personal health information seeking and management, health communications, and health decision support [13]. However, cancer survivors’ self-management and technology adoption behaviors can be complex and have not been fully understood. This study found that less than one-third of cancer survivors used eHealth or mHealth applications for cancer information seeking, access to personal health information, or exchanging medical information with health care professionals. Cancer survivors have a relatively lower mobile device ownership than American adults (60% vs. 68%) [14]. One possible explanation may be because that cancer survivors tend to be old (46.3% are 65+ years old). Among all cancer survivors, the percentage of mHealth apps owners is low (23%). However, among those survivors who had mobile devices, they were actually more likely to install mHealth apps than general population who have mobile devices (64% vs. 58%) [15]. The proportion of cancer survivors who used mHealth apps to help achieve health goals or treatment decision-making is similar as that in the general US adult population [16].

Although predictive factors of using eHealth/mHealth applications for self-management were slightly different depending on the type of technologies and self-management processes, survivors’ technology use were mainly associated with their socio-demographic characteristics, such as age, education, marital status, employment status, and household income. Younger, higher educated, married, employed, and higher income survivors were more likely to use eHealth/mHealth applications for self-management, which is congruent with the literature [13-16]. Some cancer-specific factors were found to be associated with survivors’ online cancer information seeking, and communication with health care professionals. It is understandable that newly diagnosed cancer survivors and survivors who were still on active treatment have tremendous needs for health information in order to understand the disease, and deal with consequences of diagnosis and treatment [17]. This study also found that cancer survivors who believed that everything causes cancer were more likely to look for cancer information online. This finding is inconsistent with a previous report that beliefs in everything causes cancer was not associated with cancer information seeking in general population [18]. The potential interpretation may be because cancer survivors are more motivated to obtain cancer information in order to understand their diagnosis of cancer than the general population.

Cancer survivors’ use of mHealth apps for self-management was found to be associated with their BMI and rural residency. As more than half of cancer survivors were overweight or obese, and many weight loss apps were integrated in smartphone or available for free download [19], it is understandable that cancer survivors would use mHealth apps to help achieve a health-related goal, such as losing weight or increasing physical activity. Although rural residency was not found to be associated with mHealth app use in the general population [16], cancer survivors living in rural areas seem to benefit from their increased access to health services and health information through mHealth technology [20].

This study did not find any association between race and use of eHealth/mHealth applications. This is not consistent with research on the US general population, which indicates that African American have higher odds of using the mHealth application for achieving health goals and treatment decision making than whites [16]. It is unclear whether cancer health disparities play a role in survivors’ use of mHealth technologies for self-management, which will need to be further explored. It is interesting to notice that self-efficacy, one of potential mechanisms indicated in many self-management interventions, was not found to be associated with cancer survivors’ use of eHealth/mHealth applications for self-management in this study. This finding is inconsistent with the report from the general population [16]. Cancer survivors’ self-efficacy to self-manage can vary widely according to the illness-related tasks [21]. However, cancer-related self-efficacy was not specifically measured in the HINTS survey, which was a potential limitation of the study.
There are a few other limitations in this study. First, only bivariate analyses were conducted to explore associations between potential factors and outcome variables. Some survey questions had a small number of responses from cancer survivors. For example, only 41 survivors reported that they had used mHealth apps for achieving a health-related goal. Therefore, the jackknife replication method was not able to be conducted in a multivariate regression model to calculate design-adjusted standard errors [12]. Although findings of the study tend to be preliminary, significant factors identified by bivariate analyses would contribute to the final selection of potential predictors in future multivariate analyses. Second, although a self-management theory was used to guide the consideration of potential factors for cancer survivors’ use of eHealth/mHealth applications for self-management, due to the limited number of survey questions available, some constructs in the theory could not be operationalized by measures in the survey. It is also possible that some potential factors may not match exactly with theoretical concepts. Last, survey data were collected about two years ago, which may undermine survivors’ technology adoption for the present day.

Conclusion

This study described cancer survivors’ acceptance and actual use of eHealth/mHealth applications for self-management, and revealed high acceptance of eHealth applications and relatively low adoption of mHealth apps for self-management. Less than one-third of cancer survivors used eHealth/mHealth applications for self-management, which may be limited by availability of technologies. A few predictive factors of using eHealth/mHealth applications among cancer survivors were different from those identified for the general population, with the exception of socio-demographic predictors, such as age, marital status, employment, and income. In addition, cancer-specific factors were identified to be significantly associated with survivors’ use of eHealth/mHealth applications, indicating that cancer survivors may have unique needs for their use of technologies for self-management. Future studies with a larger sample size will be needed to further explore the predictive model for cancer survivors’ acceptance and use of eHealth/mHealth applications for self-management.

Abstract

South Korean population has been aging at an accelerated rate in recent years and the country will be a hyper-aging nation at 2020. One important issue in an aged society is higher rates of chronic disorders among the population. One of the best means to prevent an increase in severity of chronic disease is making patients exercise regularly. In this paper, we present a mobile app for senior citizens that provides daily exercise recommendations an receive tailored service related to a chronic disorder. In this app, pace (BPM) of played music is regulated to encourage patients to fulfill their daily exercise goal. The combination was constructed by using suggestions of World Health Organization and Korea Sports Promotion Foundation. Through our app, users are guided to exercise daily and regularly with appropriate exercise intensity. Patients can deal with their chronic disorders via our mobile application with increased physical activities.

Keywords:
Elderly; Chronic disease; Physical Activity; Mobile Health

Introduction

The Organization for Economic Cooperation and Development (OECD) reported that life expectancy at birth and the amount of increase in life expectancy generally have been on the rise globally. For example, the life expectancy of a newly-born baby in 2009 is 11.9 years longer than that of a baby born in 1960 [1].

WHO reports that people over 65 comprises 11.8% of South Korea’s population and 88.5% of this population suffers from one or more diseases or disorders that are chronic [2]. Explosion of aged population let the rate of chronic disease in the population increase and would pose challenge to medical services, social welfare system, and the economy of South Korea.

This paper proposes a funny app that could help reduce chronic disorder among elderly population. It helps the user to define their exercise goals and work out with songs at measured BPM. We conducted experiments to verify if this app is effective in increasing user’s exercise activity.

Methods

In 2010, World Health Organization presented Global Recommendations on Physical Activity for Health, which promotes physical activities for world’s population to reduce cancer, strengthen cardiovascular system, metabolism, and musculoskeletal system.

![Figure 2 – An excerpt from World Health Organization’s health recommendation.](image)

Table 1 lists a few disorders that can be alleviated with exercises as recommended by WHO and KSPO. Medical research supports the selection of exercises.

</tr>
</tbody>
</table>
During aerobics exercises, adequate BPM of music was found to improve oxygen uptake, respiratory exchange rate, minute ventilation, and carbon dioxide exhalation [6].

The issue is that measuring exercise capabilities requires various physiological indices. Among them, heart beat rate and maximal oxygen uptake are most widely used.

</tbody>
</table>

In Table 1, PssMAX (Personal Speed Step MAX) is a scale to measure subjectively experienced exercise exertion, and it is calculated based on the speed, distance, time, and the number of steps measured via Samsung SmartPhone health App.

To measure PssMAX accurately and reliably, advanced medical instruments are necessary along with trained professionals. However, this is costly, time-consuming, and hardly practical for the majority of elderly population, hence we opted for PssMAX, which can be readily estimated with a simple smartphone. Instruments that measure such indices are not only expensive but also requires trained professionals for measurement of these criteria in indices, hence RPE (rating of perceived exertion) is popularly used as an alternative.

Borg’s table as shown in Figure 3 can be adopted for RPE scores. It offers the benefit of subjectively experienced exertion of exercise and it could supplement heartbeat rate-based scales. In short, RPE score can easily be used for general public to rate how strenuous a given exercise is.

The goal of the proposed app is promoting sustainable physical activities customized for those who suffer from chronic disorders. Presenting a simple fact alone that physical activities could alleviate chronic disorder does not automatically increase physical activities. This is true not only for elderly people but also most of the people in general. This point could be addressed with elements that are entertaining. ‘Entertainment’ is defined as ‘the action of providing with amusement or enjoyment’ according to Oxford English Dictionary. Entertainment enriches life and helps sustain it meaningfully.

Entertainment is one major benefit that elderly take from information technology [5], and if an element of entertainment could be added to exercise, users are more likely to use the service. With this line of thought, we added music to help users get motivation.

The relation between the tempo of given music during aerobics exercises and change in the body of exercising individuals has been explored among elderly women living in Seoul [6].

One participant group exercised with slower songs of 66 BPM (Andante), another group with faster songs of 132 BPM (Allegro), and the control group exercised 3 times a week for 12 weeks. At the end of the period, both exercising groups had reduced body weight and body fat and increased muscle mass while the control group showed less significant body fat reduction and increased body weight.
• Applications: One or more applications that use Motion.
• Motion: Motion components for managing specific pedometer and activity events.
• MREngine: Motion components for providing Motion with call motion events.
• SContext: Motion components for providing Motion with pedometer and activity events.

Figure 5 – Motion Architecture.

S Motion is controlled by the Application module. It takes exercise data from SensorHub module via Motion SDK Interface. The exercise data contains the number of steps taken, moved distance, time, speed, and so on. Whenever there is an update to the exercise data, the data is transmitted to the Application through Motion SDK Interface. The following modules were used in implementing our service: Smotion, SmotionPedometer, SmotionPedometer.Info Class, and SmotionPedometer.ChangeListener Interface.

Figure 6 – Motion classes and interfaces diagram.

Samsung Digital Health helps developers to synchronize health data with S Health 4.x safely and to create useful health applications. The health data framework keeps and provides users health data of various data types safely. Health data from a specific source device that has various sensors such as pedometer, accelerometer, or heart rate sensor is inserted based on the unified data unit, read, updated, or deleted through the health data framework.

The S Health Service package provides the tracker feature to show users health data information appropriately on S Health 4.x.[8].

Figure 7 – Samsung Digital Health Service.

The overall architecture of S Digital Health is shown in Figure 7. Permission to access S Health Data Type and S Health Data Store is managed with Health Data Package. The Application is granted access permission and processes the exercise data in the form of S Health Data Type when the user has paused or finished exercise and stores the data in Health Data Store database module. Our mobile app includes a service module that provides exercise data recorded through S Health Service Package. To implement this service, we used the following classes: HealthDataStore, HealthPermissionManager, TrackerManager, TrackerInfo, HealthDataResolver, and HealthDevice.

When the app is launched (Figure 8), an exercise guide is presented based on user preference as specified in the Preference menu. The user could save basic user information,
the type of chronic disease/disorder, and maximum limit for exercise exertion in ‘My health data’.

Results

To test the effectiveness of our mobile app, we contacted a local church and asked elderly congregation members to participate in our experiment. A male and a female seniors aged between 65 and 70, and also a male and a female between 71 and 75 participated. Three of them had a different chronic disorder. Their profiles are shown below.

The result showed that music contributed to an increase in physical activities by the participants.

![Image of participant profiles]

**Figure 9 – PssMax data measured for participants.**

<table>

<td>80%</td>
<td>84</td>
<td>3.6 km/h</td>
</tr>
</tbody>
</table>

As shown in Figure 9, we had our participants either run or walk fast strenuously for one minute and measured PssMAX with our app.

Participant B had chronic high blood pressure and hyperlipidemia at the time of experiment, and we set the exercise mode to the easiest one, tailored for high blood pressure patients.

To maintain exercise exertion at 60% of PssMAX, the person has to take 113 steps per minute at the speed of 5.46 km/h. The person has to take 4,520 steps for 40 minutes.

Participant B took 4,091 steps, which is 9.5% lower than recommended amount, without running our app, while this person took 5,058 steps, 11.9% more than recommended amount.

Table 2 shows recommended exercise goals based on each participant’s PssMAX value as determined by the type of chronic disorder the participant has.

</tr>
</tbody>
</table>

**Figure 10 – Summary of PssMax survey results.**

The participants were asked how satisfied they were with the service on a 1-to-5 Likert scale, where 5 means most satisfied and 1 means not satisfied at all.

Our participants responded that walking while listening to music is an effective way of exercise, and combining exercise and music makes them energetic and happy.

They also indicated that measuring maximum exercise exertion with their own smartphone rather than advanced instruments is very convenient.

Discussion

Accurate measurement of maximal exercise exertion requires costly instruments and trained professionals. In addition, the average income of elderly population is not high enough to purchase these.

Your comment:
justify the cost, hence such devices are not easily accessible in everyday use for them. PssMAX offers only a ballpark figure, which is its most obvious limitation.

Just with a smartphone, numbers such as heartbeat rate, blood sugar level, and blood pressure cannot be easily measured. However, many tools that measure these metrics are on the market as wearable devices. Once such devices are connected with smartphones, health apps such as ours could utilize them for improved measurements. Speed, distance, and time can be obtained with the sensors built in smartphones. Certain metrics can be measured more accurately in the future with further development of smartphones.

It is true that short time heavy exercise is more effective than continuous light load exercise, and it is also included in ACSM's physical activity recommendation (over 65 years old) [9].

However, it is important that ACSM recommends increasing the maximum amount of exercise load and time that elderly can do if they are unable to perform heavy exercise because of chronic disease and physical limitations.

Conclusion

The main contribution of our research is that users are guided to exercise with sufficient exertion by using an easy-to-measure scale of PssMAX. Eventually, users’ chronic disorders can be managed properly through increased physical activities.

Our mobile app is different from other existing health apps by providing exercise plans that reflect the user’s exercise profile and chronic disease/disorder.

In the future work, more sensors could be added to collect user’s exercise data. Music selection could be further tailored for different types of chronic disease/disorder.

Development of Parkinson Patient Generated Data Collection Platform Using FHIR and IoT Devices

Dae-Young Kim, Sun-ho Hwang, Min-Gyu Kim, Joon-Hyun Song, Sin-Woong Lee, Il Kon Kim

School of Computer Science & Engineering, Kyungpook National University, Daegu, Korea

Abstract

Internet of Things (IoT) devices can be effectively used in cases where continuous observation of patients is required, such as Parkinson's disease. This is due to the characteristics of the IoT (Internet of Things), which allows data to be measured and transmitted at any time, anywhere. In this study, we developed a health data collection platform that stores and transmits the foot pressure data of Parkinson patients using FHIR (Fast Healthcare Interoperability Resources). The platform can be used to collect the foot pressure of a large number of Parkinson's patients. Based on the accumulated data, it is possible to identify abnormal behaviors such as walking pattern, tilt and instability of stride length in patients with Parkinson's disease. Based on the results of this study, accurate diagnosis and treatment of Parkinson's disease can be made.

Keywords:
Electronic Health Records; Parkinson Disease

Introduction

IoT device can measure various data regardless of time and places. Thus individual who uses IoT devices can easily check and store data. At the same time, the postwar generation starts to retire and preventive medicine has advanced a lot recently. This results in increase of interest in health and desire to manage one's own health data.

Thanks to this situations IoT healthcare device market is growing at rapid pace. IoT healthcare device installation expected to increase greatly from 46 millions in 2015 to 161 millions in 2020 [1]. With this, absolute amount of data measured by IoT healthcare device is growing fast

This is consistent with the current situation in which big data and machine learning are in the spotlight. However, the absolute amount of health data has increased, but there are very few data that can actually be used for big data and machine learning.

The main reason for this is the absence of a standard health data collection platform. Some manufacturers collect health data which is measured in their products through their own cloud services, but their system rarely follow international standards.

Machine learning and big data are very sensitive to data types and formats. If health data collection platform collects data without using a international standard, data from the platform can not be used for machine learning and big data because most of user of the platform enters data without conforming to the data type and format specified by the platform.

Health data collection platform with FHIR can solve these problems above. It’s easier to inform platform users with FHIR because it’s international health data standard. Validation of data is possible with FHIR, so it is possible to sort out data that does not conform to the standard and obtain good quality data. As a result, this guarantees health data interoperability.

In this study, we would like to develop a standard platform that collects and stores health data measured by IoT healthcare device and provide anonymized data by RESTful API method. To this end, we adopted the FHIR, which is being developed as a next-generation medical information standard in HL7, as a data transmission standard. We anonymized health data because it contains sensitive personal information. We hope that this anonymized health data can be used in various studies. In order to actually apply this platform, we collected health data measured by the foot pressure sensor.

The foot pressure sensor is used to identify patterns of behavior such as abnormal stride and tilt in Parkinson's patients. The measured data can be used to compare the patient's foot pressure data with the patient's condition. A steady state analysis of Parkinson's patients and ongoing feedback are helpful in improving the patient's abnormal behavior pattern [2].

In this study, we also present how the standard platform can contribute to continuous observation and feedback of Parkinson's patients. Based on this, we would like to show how a health data platform can provide services to data providers.

Methods

Related Studies

HL7 has been developing FHIR (Fast Healthcare Interoperability Resources) as a next-generation medical standard. FHIR is suitable for IoT devices and wearable healthcare devices with low processing power due to less usage of data used for health data transmission than other medical standards such as CDA [3].

LOINC is common language for clinical and laboratory observation. It’s aim is to provide universal codes and names that provide the global lingua franca for identifying tests and observations [4].

HAPI FHIR is an open source FHIR library led by the University Health Network. This is a Java-based library, so it works well with the Java Spring framework.

When disclosing data, personal identification information such as social security number or name must be removed to protect
privacy. The data anonymization method can be classified into simple anonymization through elimination of semi-identifiers, heuristic anonymization in which detailed information is hidden through some rule or human judgment of the values corresponding to semi-identifiers, anonymization through privacy model and algorithm [5].

Foot pressure sensor: Parkinson’s disease is accompanied by several abnormal behaviors (slow motion, faceless face, etc.) due to the loss of neurons in the brain [6] In addition to biopsy, behavioral analysis can briefly confirm the patient’s condition. We developed and applied a foot pressure sensor to monitor the abnormal behavior pattern for a long time and to identify the gait that can form more accurate diagnosis and prescription through big data formation for the patient.

Health data collection platform

IoT healthcare devices can measure various types of health data. Examples of data that can be measured include Pulse and Oxygen in Blood (SPO2 and Heart rate), Electrocardiogram (ECG), Blood pressure, Electromyography (EMG), Glucometer, Body temperature etc. In this study, the foot pressure was measured and applied to a standard platform.

An overview of the standard health data collection platform is shown in picture above. The platform consists of IoT Device, Local PHR, Raw health data Server (Remote PHR), and Public data Server.

IoT devices are connected to a PC or smartphone that acts as a local PHR via Bluetooth to transmit measured health data. The user can send the data stored in the local PHR to his raw health data server with his consent. Local PHR generates user health data in FHIR standard format and transmits data to Raw health data server. When converting health data into FHIR format, LOINC code was used as a standard for measured values and measurement positions.

Raw health data server acts as a remote PHR repository. The user can store and query health data only for his/her data, and the server provides functions for this to the RESTful API. Then the raw health data stored by the user is transferred to the server through the anonymization process.

In this study, data is anonymized by simple anonymization by removing the quasi-identifier. We generated a random string of 14 digits consisting of integers from 1 to 9 and letters a to z and used it as an identifier for the anonymous user (ISO/TS 25237:2008 Health informatics - pseudonymization). The original identifier and the identifier that is being anonymized are managed as a separate table in the database of the raw health data server. This allows the measurement data for the same user to be continuously updated.

Then, public data server converts the health data stored in an anonymized form into the FHIR format and then releases it to the public through the RESTful API.

Both Raw health data server and public data server were developed as Java Spring framework on Heroku cloud service and HAPI FHIR Library is used for manipulating FHIR resources.

Foot pressure sensor

The foot pressure sensor is attached to the sole of the shoe by four pressure sensors, and the user's foot pressure is self-measured. The position of each sensor is shown in Figure 2 [7].

The pressure data measured at the foot pressure sensor is stored in the Android application, which is the patient’s local PHR repository. The stored data is converted to the FHIR format when the user agrees, and then transmitted to the Raw health data server.

Foot pressure data of 10 healthy persons and virtual foot pressure data of 10 patients with Parkinson’s diseases were measured using a foot pressure sensor. The gait of patients with virtual Parkinson’s diseases was measured by imitating the gait by referring to the article [8] that studied the characteristics of the gait of the patient with Parkinson’s disease. Each individual walked 10 seconds on a plain without slope and transmitted foot pressure data to the Raw health data server at 0.1 second intervals.

In order to store the measurement data in the Raw health data server, it is necessary to store the measurement data after registering the patient’s basic information. Patient information uses Patient resource of FHIR and measurement data uses Observation Resource. The Raw health data server then anonymizes the data and sends it to the public data server.

Parkinson analysis from foot pressure data provided as public data

The public data server uses the Bundle Resource of the FHIR to provide public data in chronological order. Researchers studying Parkinson’s disease can use anonymized user information and foot pressure data from a public data server in a variety of ways.

In this study, we derived data on the order of movement of the center of gravity and the distribution of plantar pressure from the foot pressure of anonymous Parkinson’s patients and healthy persons. The center of gravity according to the movement was compared with the time when the first pressure was applied to the four sensors, and the pressure distribution of the sole was compared with the intensity of the pressure applied to each of the four sensors. As a result, we could find the difference between the foot pressure change and the foot pressure distribution in general and Parkinson’s patients.
Provide services to the patient based on the analyzed data. To provide an example of the use of health data collection platform, we have developed an application that provides a service to compare the data of Parkinson's patients and the general public based on the above analysis and to analyze the progress of the treatment.

The application compares and analyzes the foot pressure data from the IoT healthcare device of Parkinson's patients against the general foot pressure data provided by the public data server. On the basis of this, the medical staff can know the current condition through the self-measurement of the patient, and can simply summarize the opinion on the progress of the treatment compared with the past patient's record. In case of an emergency, user can contact the doctor in charge. The information on the treatment progress and the bio-signal is stored in the local PHR repository so that the physician and the guardian can read it at any time.

Results

The FHIR Patient resource is generated to transfer patient information from the local PHR to the Raw health data server as follows.

```json
{
  "resourceType":"Patient",
  "identifier":[] {
    "value": "910523-2895112"
  },
  "name":[] {
    "use": "official",

}
```

Figure 3 - Patient resource

The resident registration number was used as an identifier of the patient and basic information such as name, phone number, sex, date of birth, etc. was stored.

Observation resource is generated to send the foot pressure measurement data from the local PHR to the raw health data server.

The patient identification number was used to identify the measurement value of the patient and the data was stored in chronological order including the measurement time. The Loinc code for the Body site and Component is not mapped yet.

Public data server uses FHIR Bundle resource to provide the anonymized foot pressure data measured at the foot pressure sensor. Due to the characteristics of the Bundle resource, multiple components can be stored, allowing the researcher to transfer large amounts of health data at a time.

Figure 4 - Observation resource

FHIR StructureDefinition resource describes a structure - a set of data element definitions, and their associated rules of usage. This resource is used to describe the underlying resources, data types defined in FHIR, and also for describing extensions, and constraints on resources and data types.

The base FHIR specification describes a set of base resources, frameworks and APIs that are used in many different contexts in healthcare. However there is wide variability between jurisdictions and across the healthcare ecosystem around

```xml
<?xml version="1.0" encoding="utf-8"?>
<StructureDefinition xmlns="http://hl7.org/fhir">
  ...
  <base value="http://hl7.org/fhir/StructureDefinition/Patient" />
  <differential>
    <element>
      <path value="Patient" />
      <type>
        <code value="Patient" />
      </type>
    </element>
    <element>
      <path value="Patient.identifier" />
      <definition value="An identifier for this patient" />
    </element>
    <element>
      <path value="Patient.identifier.id" />
      <representation value="xmlAttr" />
      <definition value="unique id for the element within a resource (for internal references)" />
    </element>
    ...
  </differential>
</StructureDefinition>
```

Figure 5 - Patient StructureDefinition
practices, requirements, regulations, education and what actions are feasible and beneficial. For this reason, further adaptation is required to particular contexts of use.

As a consequence, StructureDefinition resources for Patient and Observation resources are defined are outlined in Figures 5 and 6.

These two StructureDefinition resources not only represent a structure constrained or extended from basic FHIR specification, but also can be used to validate FHIR resources being exchanged for the purpose of enhancing the degree of interoperability.

Data were provided as shown in Figure 6 and Figure 7 with public health data on foot pressure. We record the point at which the pressure value applied to the foot pressure sensor initially has a value at the initial value (0) to analyze the pattern of the gait pattern. In general, the pattern of walking changes regularly from 1 → 2 → 3 → 4, but the patterns of Parkinson’s patients are not known because Parkinson's pressure is applied in an irregular order [9]. We found differences in gait patterns among the general population and Parkinson's patients. Also, by comparing the pressure of each sensor at the same time, the difference in foot pressure distribution between the general and Parkinson’s patients was also found.

Figure 7 is a graph of the mean of the pressure values applied to the four sensors over time while a normal person is walking. In the case of Parkinson’s patients, pressure is uniformly applied to the remaining sensors except the second sensor. This can be interpreted as an unusual step where the center of gravity is constantly biased forward. Using the difference in gait patterns of these patients, the current state of the patient can be diagnosed by comparing with the normal control group.

Figure 8 is a graphical representation of the mean value of pressure applied to four sensors over time while a Parkinson patient is walking. In the case of Parkinson's patients, pressure is uniformly applied to the remaining sensors except the second sensor. This can be interpreted as an unusual step where the center of gravity is constantly biased forward. Using the difference in gait patterns of these patients, the current state of the patient can be diagnosed by comparing with the normal control group.

Discussion

Using the health data collection platform developed in this study, a large amount of accumulated health data can be utilized by researchers and medical personnel in various researches. Our ultimate goal is to provide beneficial services based on the results of research using this platform, and to contribute to the promotion of human health.

From this point of view, applying this platform to actual Parkinson’s patients is expected to provide customized services to patients with Parkinson's disease based on the results of using the foot pressure data. The mobile application can help patients to quickly identify their condition, instantly adjust the supply of drugs under test, and help them improve treatment methods, such as understanding the course of treatment based on objective health data.
In order to implement this, there are additional things to be to
the platform: linkage between hospital system and raw health
data server, advanced data anonymization algorithm.

Improvements in terms of IoT devices include measuring heart
rate, blood oxygen saturation, EMG, blood pressure, and vari-
ous other health data to enable more comprehensive patient sta-
tus confirmation.

As these improvements are implemented and the actual data of
Parkinson patients are constantly accumulated on the platform
and enough data is formed, it is possible to make more ad-
vanced research and diagnosis. Based on this, it will be
possible to perform gait correction and early diagnosis of
Parkinson's disease and correct treatment can be done.

Conclusion

The reason why many health data are not used in the medical
field is that the health data is collected without using the inter-
national standard. If the data is collected without conforming
to the international standard, it is impossible to verify the
input data, and the collected data shows increased errors. In
addition, all does not share standards set up individually, so
additional processing of the data is required when the data is
utilized be-cause of the lack of versatility.

To solve this problem, this study proposed health data
collection platform that collects and provides health data using
FHIR, the next generation medical standard. In order to apply
the plat-form to the medical field, we dealt with patients with
Parkinson’s diseases and measured the patient’s footsteps
through the foot pressure sensor.

Developing a Mobile Wellness Management System for Healthy Lifestyle by Analyzing Daily Living Activities

Chae-Gyun Lim, Zae Myung Kim, Ho-Jin Choi

School of Computing, KAIST, 291 Daehak-ro, Yuseong-gu, Daejeon 34141, Korea

Abstract
It is important to protect health and improve quality of life for people, without causing them inconvenience in today’s world. Since most people are living a busy life dealing with various activities at work, school, or home, there is a need for systematic analysis of their life patterns. However, since person’s life patterns could change depending on ambient environmental factors, an effective management scheme to specify one’s state is required. We propose a method, in this paper, to support and enhance the personal healthy life patterns by analyzing the daily life data that has been continuously recorded by wearable sensors, such as activity trackers. We implement a mobile wellness management system by learning RNN-based user’s lifestyle model, and developing behavior recommendation using greedy policy. We also consider user context and feedback to personalize each user’s lifestyle.

Keywords:
Health promotion; Life Style; Fitness Tracker

Introduction
Recently, Quality of life (QoL) is an important concept for general public, as well as researchers. Researchers have increasingly conducted research to improve QoL and daily lives of people. The QoL is defined as a subjective assessment of individual’s well-being that includes both physical and psychological aspects of daily living [13]. Specifically, in case of patients with chronic diseases, such as diabetes, QoL in the short-term could be poor and may affect the motivation to manage one’s own health in the long-term [10, 15]. In such situations, it is required to provide appropriate treatment concerned with not only long-term, but also short-term aspects. As quality of daily living is related to QoL, it is frequently assessed in various questionnaires of psychometric assessment tools [6, 13]. However, most people have different quality of daily living due to the diversity of their living environment. To analyze and model each individual’s lifestyle, we need to monitor entire sequences of activities of the person’s daily life over time. Nowadays, there are many wearable sensors to collect behavioral and physiological data from users’ daily living activities. Some researches have used these sensors that collect physiological signals, such as blood pressure, heart rate, heart rate variability (HRV), and skin conductance, in order to recognize user’s affects [2; 5; 7; 12; 14].

Activity trackers, like pedometer, are useful tools to support tracking movements and manage users’ activities by utilizing a cloud service on Web or mobile app. In general, activity trackers are wearable devices, such as wristband or belt, and they send various types of collected data to a smartphone and/or a server [6]. The stored data can be visualized in various ways, such as statistics of movements or graphical charts showing trends, to motivate users to reach their goals.

Today, activity trackers track multiple types of data, including step counts, movement speed, distance, heart rate, and sleep patterns. Sometimes, exercise or dietary habits can also be recorded on a mobile app or Web site that manufacturers support. Fitbit is one of the famous brands in activity tracker available in the market. It offers many kinds of wristband-type devices that can display various states, such as active state, sleep mode, or notification arrival. Jawbone device and mobile app work on several smartphone platforms, and provide attractive features to track user’s movements, heart rate, sleep patterns, and personal records on diet and activity. It can also indicate detailed information including awake time and the level of sleep (deep or light sleep).

Therefore, we choose the Jawbone’s activity trackers for our experiments. Two main reasons of our choice are as follows:
1. They apply three bio-impedance signals, such as heart rate, respiration, and galvanic skin response (GSR), to collect data of user’s activities; and
2. They track not only daily activities, but also detailed levels of patterns while the user is sleeping.

In order to utilize more useful services in combination with existing healthcare services, there have been various attempts to model the state of physical information of a particular user along with underlying measured values from various sensors and devices. Pande et al. [9] and Bouarfa et al. [3] conducted a study to model the energy consumption of a person according to the activity, and Cheng et al. [4] performed a study to model changes in heart rate during the course of various activities. Austin et al. [1] and Lipton et al. [8] attempted to accurately model and predict user’s heart rate; thereby, identifying medical important situations, such as heart failure.
However, this research has focused on analyzing the user state, on the basis of the present time, based on data already collected from an external device, such as a wristband-type sensor. It is, however, difficult to predict a future activity or change in situation for the user in order to guide a systematic health promotion plan. If user’s activity pattern is predicted through user modeling using machine learning technology, such as DNN, it is possible to suggest proper activities at an appropriate time. Also, in order to automatically determine whether the activity is performed without causing inconvenience to the user, it is necessary to be able to observe the change of the user’s activity or situation at the relevant time, and obtain feedback on the results of the activity recommendations.

In this paper, we propose a personalized wellness management system based on mobile environment to improve lifestyle quality by analyzing the recorded time series data in daily life. Figure 2 shows overall concept of our proposed system. First, we collect three types of time series data, such as heart rate, step counts, and amount of burned calories. We also log the changes of the user’s location context. Based on these collected data items, we analyze and extract user’s lifestyle patterns that will be used as input features. To construct an appropriate model to represent the characteristics of user’s daily lifestyle, we apply a recurrent neural network (RNN) model. Lastly, we recommend healthy behaviors for the specific user, underlying the lifestyle model built in previous step. For each recommendation, the user can give particular feedback to adapt the RNN model for supporting personalization to the user’s lifestyle.

**Methods**

In this section, we explain overall architecture of our mobile wellness management system in detail (Figure 3). First, we describe how our system analyzes user lifestyle, and models an individual’s lifestyle patterns based on the time series data that have been obtained by wearable sensors. Second, we explain a process of activity recommendation to enhance user’s wellness by utilizing the lifestyle model. Third, we introduce functionality of our mobile system, and illustrate user perspective using Android platform.

**Collecting time series data**

The wearable device, Jawbone UP3, collects and provides four types of time series data (i.e. sleep pattern, heart rate, step count, and amount of burned calories) from the user who is attached to the device. While only sleep patterns have nominal values over time, such as awake, light, or deep sleep, other three series have numeric values. In the data scheme of UP3, sleep pattern and heart rate are managed by different entities separately; however, both step count and burned calories are stored in a single entity named as ‘moves’. These are written in JSON (JavaScript Object Notation) format. Here we show partial examples for each data gathered by UP3.

- **Sleep pattern:**
  ```json
  [{"depth":1, "time":1448227726}, {"depth":2, "time":1448228457},
   ...
  {"depth":2, "time":1448244340}, {"depth":3, "time":1448245505}]
  ```

- **Heart rate:**
  ```json
  [{"time_updated":1460041251, "resting_heartrate":62, "sleep_ranges":[]},
   {"bg_move_day_hr_ticks":[]}, {"hr":67, "time":1459955996},
   "{hr":69, "time":1459993357},
   ...
  {"hr":55, "time":1459932281},
   {"xid":"piqj71jQzD8o4kfqUacmm1NTWAkPuB x_",
    "type":"heartrate"}]
  ```

- **Step count and burned calories:**
  ```json
  [{"time_completed":1445712639, "distance":3, "calories":1.15767812729, "steps":5, "time":1445712576, "speed":0.047619048506},
   ...
  {"distance":2, "time_completed":1445782637, "calories":1.17605400085, "steps":7, "time":1445782573, "speed":0.03125}]
  ```
Extracting lifestyle patterns
The raw data from UP3 should be preprocessed before fitting the RNN model. Due to the difference in data type, we analyze three time series data, i.e., heart rate, step count, and burned calories. The sleep patterns are used for context information. We create three separate vectors for each collected data. The changes of user’s location context provide potential clues regarding daily activity and lifestyle pattern of the user. For example, an officer’s activity logs may show that there is a regular pattern between working place and home, such as “this user arrived to the working place at 9 a.m. everyday.”

The patterns of user’s daily lifestyle can be extracted as a multi-dimensional vector consisting of statistical metrics (sum, average, min, or max for every minute) of the collected data. Because our goal is to characterize a daily pattern for the user, we limit the data size to 24 hours while calculating features. In addition, we thought that durations shorter than one minute (e.g., every second) are not useful to represent a daily activity. These data vector patterns are used as input to the RNN model.

Learning RNN model
The RNN model is an artificial neural network, which has a directed cycle between units [11]. This model is appropriate due to the characteristics, where each unit of RNN has a time-varying activation with real-value. Figure 4 shows the RNN structure used to build the lifestyle model. In our model, each hidden layer will be calculated from each value of the given time series data \( T_i \) where the number of time steps is \( n \) and \( i \)-th time step is \( T_i \). The model used the dense function with ReLU (Rectified Linear Unit) when obtaining the output values in the last layer. By learning the three individual feature vectors (i.e., heart rate, step count, and burned calories), we can construct personalized lifestyle model for the particular user’s daily living activities.

![Figure 4 – RNN model to learn each time series data](Image)

Modeling individual’s lifestyle
We obtain quality of lifestyle for the user by combining the collected activities of daily living and the outputs of learned RNN model. This RNN-based lifestyle model is personalized to the user’s lifestyle. Therefore, each lifestyle model can be a baseline of the user’s wellness, and can be utilized to make recommendations in the next stage.

Behavior recommendation
Next, our system have to decide adequate healthy behaviors based on the user’s lifestyle model. Because the user’s life depends on his or her own lifestyle patterns, considering context information of the user, such as location or time availability, facilitates to suggest proper healthy behavior to the user.

Figure 5 shows a flow chart illustrating procedures of behavior recommendation and adaptation to the user. This flow starts after constructing RNN-based lifestyle model for the user. First, we can obtain the user’s upcoming activeness based on the lifestyle model. For instance, three types of values — heart rate, step count, and burned calories — can be predicted for the upcoming one hour from the current moment. We, then, check whether the predicted values of activeness are lower than the thresholds corresponding to each data type. If it is true, our system generates new behavior recommendation for the user to increase the amount of future activity.

Before suggesting new behavior, we consider the user’s current location context to choose what activities are suitable. For example, walking around is sufficient if the user is just coming from the lunch near the workplace, and he or she must return to work soon. Moreover, we apply greedy policy for individuals to make a decision that provide healthy behaviors. The user can send feedback to our system corresponding to the behavior recommendations in the past. There are two types of feedback: one is a flag of satisfaction, and another is whether recommended behavior is finished or not. If the user responds that he or she is not satisfied with that particular recommendation, then parameters of greedy policy in the user’s context are decreased. It means that the possibility of the behavior recommendation in the specific context is also reduced, and vice-versa. This adaptation process supports better personalization for the user.

![Figure 5 – Flow chart for suggesting appropriate behaviors to the user and adapting user feedbacks](Image)

Implementation of mobile wellness management system
In the previous two sub-sections, we explained the main steps of the wellness management system, RNN-based lifestyle modeling, and healthy behavior recommendation. Now, we describe the implementation details of our mobile app on Android platform. Figure 6 shows user interface snapshots for each functionality. The important functional features of the mobile app are as follows:

- Inquiry about the history of user’s activeness for today or a specific date.
  - The user’s activeness consists of heart rate, step count, and calorie consumption.
  - Each data of the activeness is depicted by a line chart individually.

- Recommend a healthy behavior periodically that can increase the user’s wellness.

- Manage the history of activity suggestions.

- Support to get the user’s feedback corresponding to activity suggestions.
  - There are two types of user feedback: a level of satisfaction regarding the prior suggestion, and another indicating whether a suggested activity is done or not.
Experimental Design
We have plans to collect target users’ lifestyle data by using Jawbone UP3 wristbands as shown in Figure 1. We need sufficient log of data for participants over a period of long time, at least for a few months. For logging precise data from each participant in our experiments, we asked that they follow the instructions below:
- Participants have to wear the wearable device whenever possible during the experiment.
- Participants have to answer a questionnaire of psychometric assessment tools every day.
- Participants have to give two types of feedback for each recommendation—a satisfaction level and an execution rate of suggested activities.
- When adding a new activity manually, participants have to honestly insert actual information.

The satisfaction level consists of 6-point Likert scale as follows: strongly satisfied (3), satisfied (2), slightly satisfied (1), slightly dissatisfied (-1), dissatisfied (-2), and strongly dissatisfied (-3). The execution rate $R_e$ is obtained by

$$R_e = \frac{\sum_{i=1}^{N} e_i}{N} \times 100$$

time, at least for a few months. For logging precise data from each participant in our experiment, where $N$ is the total number of recommendations, $e_i$ means the $i$-th flag of execution, and $e_i$ is 1 if the suggested activity is done, 0 otherwise.

The results of questionnaire and feedback is used to verify if our quality measure properly works.

Conclusion
Maintaining an individual’s QoL is necessary in modern society, but it is very difficult due to the variety of lifestyles. In this paper, we proposed a mobile wellness management system for enhancing lifestyle quality based on analysis of time series data that is collected from wearable sensors. User’s lifestyle patterns over time are extracted, and the RNN model is constructed by using the lifestyle features. Finally, our system makes suggestions of healthy behaviors underlying the learned RNN model depending on particular user’s lifestyle.

In future work, we will conduct long-term experiment with several participants for collecting their activity logs of daily living and analyzing their lifestyle patterns in order to verify whether our management system has enough usefulness.

Guidance Through Use: Value as a Pathfinder in e-Health Services Implementation

Bertil Lindenfalka, Vivian Vimarlund*a, b

a International Business School, Jönköping University, Jönköping, Sweden
b Department of Computer and Information Science, Linköping University, Linköping, Sweden

Abstract

The lack of awareness and confidence in eHealth solutions among certain stakeholders creates a barrier for the implementation of eHealth services. The aim of this paper is to explore issues that promote the development and implementation of patient-centered care services for the elderly. An exploratory case study approach is applied to a eHealth monitoring service that was developed and piloted in 38 homes for the elderly in Sweden and the Netherlands. The unit of analysis, concept of ‘value-in-use’, was used in order to determine how pilot participants felt about a service of this kind benefiting them the most. The findings were then translated into actionable considerations for implementing organizations. The results indicate a need for active participation, technical support infrastructure, mobility demands, and an extension of the concept of trust in eHealth services. The knowledge presented in the study is important for decision makers, public organization strategists, and policy writers.

Introduction

E-health is a priority for the European Union (EU) and its member states [1]. Current research on the generic implementation of e-health services focuses on two things: (1) E-Health megatrends and its effects on health and social care for services in smart homes [2], and (2) removing existing barriers, such as the lack of interoperability among e-Health applications, limited large-scale evidence of the cost-effectiveness of e-Health tools and services, high start-up costs, regional differences in accessing ICT services, lack of legal clarity for health and wellbeing mobile applications, and the lack of awareness and confidence in e-Health solutions among stakeholders [1].

These challenges, in parallel with the growing number of the elderly, and the inability for many member states to give the elderly timely attention and support at the point of care have prompted EU member states to prioritize e-Health services that offer services with equal (or more) quality and effectiveness. At the same time, the re-allocation of resources and their proper use from an organizational perspective has to be allowed. This is especially the case in the member states that have publicly- or partially-funded health and social care systems.

Research in the areas of service marketing, management and service innovation, highlight the importance of the proper use and implementation of services as the fundamental basis of value creation, where exchange is but one component, along with use and context [3-5] issues are important to both private and public organizations [3; 5-10]. This exchange cannot happen without the participation of both a service provider and a service beneficiary to co-create value. The service provider and the service beneficiary are, and always will be, interconnected [3; 4]. The goal of exchange is to use the applied knowledge of others (service) as resources to better one’s circumstances. In the exchange between service systems (the provider and the beneficiary), value is determined through the use (or integration) and application of operant (and sometimes operand) resources [11]. The relationship is however, not equally dichotomous. The service beneficiary should always be considered as the most important part in the relationship. The service beneficiary decides the ultimate and final value of a service. Services are not of a purely monetary value and products are mere vessels for service distribution. All in all, all economies are service economies and value lies in use [3, 4, 7, 12]. For public sector organizations that govern developed e-Health services, it is also important to note that the value of e-Health services can be derived to society in addition to the individual service beneficiary [8]. This issue is something that current research in the field has not extensively reported on.

The aim of this paper is to explore issues that promote the development and implementation of patient-centred care services for the elderly, i.e., e-Health services, thereby addressing the barrier that “the lack of awareness and confidence in e-Health solutions among stakeholders” creates. The results of this study should be of interest for decision-makers, as well as policy writers.

The context of the study

The study was conducted in conjunction with the Healthy Life support through Comprehensive Tracking of individual and Environmental Behaviors project (HELICOPTER). The overall aim of the project was to support end-users’ health in an unobtrusive and simple way, through monitoring daily-life behaviors, and supporting end-users and their caregivers with feedback, advice, and motivation in their pursuit of a healthy and safe lifestyle. The project was directed towards people over 65 who were not suffering from any major chronic diseases or severe disabilities, but who might possibly be affected by (or be at risk of) metabolic or circulatory malfunctioning (e.g., hypertension, mild diabetes), or by mild cognitive deficits.

The piloted service consisted of placing sensors in the homes of the pilot participants. In the finalized service, (see Figure 1 for a detailed overview of the service), the users are meant to be able to choose which sensors they would like to be incorporated into their own service experience, but for the purposes of the pilot all of the sensors were installed in the participating households. The sensors included a sensor placed...
in the participant’s favorite chair/couch, one bed-sensor for sleep-pattern recognition, one toilet sensor, one wearable sensor for monitoring the participant’s movement, a sensor acting as a ‘nose’ in the refrigerator to check whether any food had gone bad, and sensors for drawers, etc. The participants also received a small computer to manage the data that was sent by sensors, a tablet to access the Helicopter service application, and what the project called a ‘snowflake’, which was supposed to act as an unobtrusive way of letting the user know whether the sensors were working or whether they needed to check the application for messages coming from the service. The tablet application was meant to act as an interface for signing, ordering the sensors at the beginning of the service lifetime and the interface where the service beneficiary could see long-term behavioral patterns, according to the information sent by the sensors.

In some of the households in the Netherlands, two clinical sensors were also included in the pilot. These were intended to establish a more concrete link to the healthcare practitioners and the healthcare system. This was intended to allow GPs who were part of the project to view the data that was collected by both the behavioral sensors and the clinical sensors, in order to investigate whether or not potential diseases could be inferred by the system. In the case of the project, focus was indicators of the early on-set of diabetes. However, due to certain technical and ethical considerations, the data collected by the clinical data sensors never actually left the sensors, i.e., no one but the person using the sensors could see what the sensors had monitored. This, of course, affected the general service process and hence the service experience.

In some of the households in the Netherlands, two clinical sensors were also included in the pilot. These were intended to establish a more concrete link to the healthcare practitioners and the healthcare system. This was intended to allow GPs who were part of the project to view the data that was collected by both the behavioral sensors and the clinical sensors, in order to investigate whether or not potential diseases could be inferred by the system. In the case of the project, focus was indicators of the early on-set of diabetes. However, due to certain technical and ethical considerations, the data collected by the clinical data sensors never actually left the sensors, i.e., no one but the person using the sensors could see what the sensors had monitored. This, of course, affected the general service process and hence the service experience.

The pilot studies were carried out in the municipality of Skövde in Sweden, and in the Eindhoven Region of the Netherlands. In total, 38 pilot studies were carried out in end-user’s homes in order to test the system. Consequently, the total number of respondents for each activity was 38 (n-max).

Figure 1 – General overview of the service process from the service beneficiary’s point of view.

Framework for the study
e-Services have been defined as any service which to some extent uses the internet for service provision [13]. Typically, four different dimensions of importance are considered in relation to judging an e-Service’s ‘value-in-use’: these are the technical, functional, temporal, and spatial dimensions [14]. The technical dimension refers to the outcome of the service interaction, whilst the functional dimension encompasses the users’ perception of the outcome of said service interaction. The temporal dimension refers to the user’s perception of the time when the service interaction occurred and finally, the spatial dimension concerns the users’ perception of the location where the service interaction occurs [14]. All of these dimensions play a key role in determining the service that is experienced from the beneficiary’s point-of-view. Additionally, one of the antecedents of ‘acceptance’, a common concept in implementation research is, use. Use is for instance, identified to be an important antecedent in implementation models such as TAM [15], UTAUT [16, 17], as well as in IS continuance research [18]. Use is becoming an even more integral factor, when success in contexts, for multiple actors are involved is to be determined [7]. In this study, we adopt the e-service ‘value-in-use’ framework [19].

Method
The study used an explorative case-study approach [20] along with a holistic case study design, where the perceived ‘value-in-use’ was the single unit of analysis. Data was triangulated by using material collected from workshops, interviews, and questionnaires [20]. All activities were performed with the pilot participants after the service had been running for at least three months in each respective household, i.e., at the end of the project’s lifetime.

Data collection procedures
Two workshops were held during the pilot. One with the Dutch participants (n=7) and one with the Swedish participants (n=9). The aim of the workshop was to get a collective view of who they thought was the potential user of the service, what they thought was valuable (and not so valuable) with the service, who was liable for what in the service and finally, what their view was of what the service could be in the future.

The workshops had the same structure in both countries, except in the Netherlands, a translator was used by the facilitator. The workshop consisted of two tasks for the participants. The first focused on the positive and negative experiences of using the service. The second task focused on the future potential value of the service.

The semi-structured interview (n=12) and the questionnaire (n=22) focused on the pilot participants’ perceived value of the e-service and what impact the e-service might have on their daily lives. In the construction of the interview guide and the questionnaire, the e-service value-based framework [19] was used so as to address all of the relevant dimensions. For instance, questions like, “Where and what time of the day did the participants use the tablet application?”, were asked. In addition, questions were asked about how they used the service and what value they could see in using the service personally. It is important to note that the questionnaire was descriptive in nature and was not intended to be used for statistical analysis. All material was translated into English from the participants’ respective languages.

The analysis was conducted using the e-Service value framework where the technical, functional, spatial, and temporal dimensions were identified. This was followed by the categorization of positive and negative value dimensions. The analysis was conducted using Nvivo software where all the material from the activities was analyzed together in accordance with the method of data triangulation [20]. It’s also important to note that feedback from the participants in the pilot was given to the service as it was piloted, i.e., potential improvements of the service would need to be considered, as well, in future development phases. The results of the study are thus based on illustrative quotes that were given by the pilot respondents and the subsequent discussion.

The pilot studies were carried out in the municipality of Skövde in Sweden, and in the Eindhoven Region of the Netherlands. In total, 38 pilot studies were carried out in end-user’s homes in order to test the system. Consequently, the total number of respondents for each activity was 38 (n-max). Table 1 shows a detailed overview of the number of respondents for each activity. In total, 10 pilot studies were...
carried out in Sweden (six single households and two couple households), and a total of 28 studies in the Netherlands (21 end users in 16 households) were included in September 2015, with an additional seven end users (in six households) were included in December 2015.

Results

The result section is divided into five sub-sections that correspond to the four dimensions of the e-Service ‘value-in-use’ framework that was applied during analysis [14, 19] and one additional dimension which was identified during the analysis.

Technical value-in-use

The technical value is determined by service beneficiary’s assessment of the outcome of the service interaction, i.e., whether the service promise was fulfilled or not. For this dimension, certain aspects of the service, such as being able to create an account in the application, finishing the ordering procedure of the sensors, changing the batteries in the sensors, and the installation of the sensors became important issues. These constituted well-defined service interactions according to the users. However, after the instalment of the sensors, it became more difficult for the pilot participants to determine when they were actually using the service and when they were not using the service. This was due to the service’s unobtrusive nature. They had to trust that the sensors were working; something which they did not like. As one participant in the Swedish workshop put it; “the value lies in knowing that I’m okay”.

Functional value-in-use

Functional value refers to the service beneficiary’s perception of a service outcome, i.e., if they found it valuable or not, and if the interaction was deemed to be value-diminishing or value-amplifying.

One value-amplifier mentioned by the pilot participants was the fact that they could access their own data on the tablet application. The data collected day-by-day was not of particular interest, but rather the longitudinal data that was collected over time, where patterns could be noticed, was of interest. As one of the participants said, “seeing that the patterns are the same is a confirmation for me that I am okay”.

A value-diminisher that was mentioned by the pilot participants was that they did not like the fact that they could not choose the technological medium with which they were to access the service interface. They felt that being forced to use the tablet was not always the optimal solution for them, because they did not like the tablet as such. Some participants wanted to be able to use the tablets they already owned, whilst others felt that this was a service which they wanted to use their computer for. Another value-diminisher was the technical malfunction during the pilot where the application could not retrieve the data that was collected by the sensors. This was something that caused the participants to respond in an unforgiving manner towards the service and some pilot participants even went as far as leaving the pilot study because of this malfunction. However, those participants who could access the data that was collected by the sensors in the application found this to be very interesting in the long term. As one participant put it, “I don’t care if my behavior changes from day to day, but perhaps week by week or month by month”, thus indicating how often she opened the application to view her behavioral charts.

One major value-diminisher was the use of the wearable activity tracker and identifier. This was used not only to measure the number of steps taken by the participant, etc. but also to identify which particular user, for instance, used the toilet in a household where two people participated in the pilot. Here the pilot participants responded that the tracker was easily forgotten in the morning since they had to charge it every night, and so they felt that the data collected was not accurate. Some participants who did not have any pockets in the clothes they were wearing (predominantly the female participants) created pouches or other solutions so as to have the tracker on them.

Spatial value-in-use

The spatial value dimension refers to the service beneficiaries’ perception of the milieu where the service interaction occurred. This does not only include the interface where the service is co-created, but also takes into account non-service parts, such as the context and other people who are involved in providing the service.

A major value-diminisher of the entire service, according to the pilot study participants, was that the sensors only worked inside their homes; their activity outside the home was not recorded. This state of affairs left them to doubt the accuracy of the activity charts and the data that was collected. One participant stated, “I could be out and about all day, shopping, picking up my grandkids and playing with them, and be very active but when I look at my chart, it says that I have been idle. Which is not true!”.

One value-amplifier that was identified was how the sensors blended seamlessly into the home. Almost all participants, when asked if they were bothered by the sensors, said that they do not even notice them anymore. They did notice them in the first week, but since then, they were considered to be a natural part of the home. When they had guests over to visit, some participants said that some guests had asked what the boxes were, but once they were explained, guests took no further notice of them. The only sensor that they did notice on a daily basis was the wearable sensor. Some remarks were made about the bed sensor too, that it could be made more comfortable.

Temporal value-in-use

The temporal value dimension refers to the time when the service interaction occurs; including time dimension when the service co-creation could be aborted mid-way and be resumed at a later stage, or if certain processes either took too long, or were felt to be too short.

With respect to the temporal value in the service, the respondents found it difficult to define the time when they used the service once the sensors were up and running. Due to the unobtrusiveness of the service, the only service interaction that actively took place, from the pilot participant’s point of view, was when they tried to access their data in the application.

In terms of installation and setting up the service, the initial answer from the participants was unanimous; this took way to long and was way too complicated. The time spent on this
activity needs to be reduced and the sensors need to be very easy to install; almost to the level of merely inserting batteries before use. It was clear, from their point of view, that a service that took this much time to set up and install was something that they would never procure without knowing that the technical support offered with the service was excellent.

**Towards Social value-in-use**

In the interview and workshops, a fifth dimension was identified. Due to the fact that the service was an e-Health service, i.e. it was a service aimed at capturing diseases early on, the pilot study participants were inclined to tolerate certain flaws, for the benefit of society. They claimed that the service could be important, for society as a whole, and that they used the service so that other citizens could receive more acute care should they need it. As one pilot participant from Sweden phrased it, “I don’t believe that we will have the resources required to accommodate everyone who needs care in the future and if we can, we should, use technology to minimize the need. It is very good”. This dimension was not sought after in the interview questions, but it did appear when the question of why one should use a service like this was asked.

**Discussion**

Certain technological advancements and a growing need for pre-emptive care services that are directed towards the elderly are two forces that are changing the context in which future health and social care services are to be delivered [2, 9, 10]. In Europe, much of the work to be done lies in empowering citizens, by actively involving them in the care process through the use of e-Health services. Historically, many of the new services that have been developed by utilizing IT are still only implemented inside the boundaries of the care organization, e.g. the hospital. The provision of Electronic Health Records (EHR) is one such service. Our knowledge of the implementation of e-Health services is founded on the premise that users can be guided, and sometimes even forced, to use newly-developed services. However, with the contextual change that the nature of future e-Health services creates, the need for generic implementation models for organizations that act outside of the physical boundaries of an organization (e.g. a hospital or clinic) has arisen.

This paper argues that, by adopting a service view and carefully considering the factors that influence the successful implementation of said service, new and valuable knowledge can be generated which can be used to promote the development and successful implementation of e-Health services. Repeatedly, the importance of using e-Health services and services in general has been emphasized [3, 5, 8, 10, 15, 17, 22]. Therefore, we have adopted a framework specifically developed for e-Services where the notion of ‘value-in-use’ is emphasized [14, 19, 21, 23]. The framework consists of four ‘value-in-use’ dimensions; the technical, functional, temporal, and spatial dimensions.

The findings of this study can be condensed and translated into the following four implementation guidelines. Given the technical ‘value-in-use’ dimension, the users experienced difficulty in determining what the actual value of the service was when it was being used. This can, of course, be explained in terms of the unobtrusive nature of the service and the lack of active participation in the co-creation of the service from the service beneficiary’s point of view. Previous research has shown that ‘activity’ is an important factor when services are co-created [21]. In terms of functional ‘value-in-use’, technological ease is still a major factor for the elderly. The need for a specific technical support line was highly anticipated. From a spatial ‘value-in-use’ perspective, the need for mobility was highlighted; all access to e-Health services should not be determined by the location in which one finds oneself. Temporal ‘value-in-use’ aspects, on the other hand, emphasize the longitudinal time perspective of the service, as well as, the need for establishing a trustworthy baseline for each user.

The above remarks can be translated into the following actionable guidelines for implementation organizations. Clearly communicate not only the value proposition for the service but also the level of activity for service provision by the service beneficiary. In terms of infrastructure, it should be noted that the need for technological maturity stretches outside pure technical dimensions and includes infrastructure for service beneficiary tech-support. In the design and development phases, the mobility aspects of the service, must be taken into consideration so that the user’s location should not be limiting factors for the provision of the service. When policies supporting the development of new e-Health services that focus on pre-emptive care are formulated, it is important to consider (for the sake of the trustworthy of the service) that the service be provided while the service beneficiary still feels healthy. Previous studies have indicated the need for trust in relation to e-Health services and online provision of health information [24, 25]. These findings highlight yet another aspect of the trust issue that is related to e-Health services in general.

In general, the findings resonated well with the e-service ‘value-in-use’ framework. However, a value dimension which the original e-Service ‘value-in-use’ framework did not highlight was the social ‘value-in-use’ dimension. Although the findings are preliminary, they indicate that for e-Health services in the public-sector context, service beneficiaries project their own usage value to a larger societal context as well. It certainly might be the case that this dimension is culturally bound, since the pilot participants live in ‘welfare states’ to one extent or another. However, it is a finding that requires further attention than that given in this paper. Suggestively by considering conducting a longitudinal case study where a fully developed e-Health service is in use.

This study has several limitations. This work only considers the ‘value-in-use’ aspects of the entire value concept, leaving the value-in-context and value-in-exchange, as described by [5] the unexplored. Future studies could, for instance, focus on translating the value aspects found connected to use to those of exchange by considering a cost-benefit analysis. However, notwithstanding these limitations, interesting results that can be translated into actionable guidelines for organizations that wish to implement e-Health services can be found.

Another limitation is connected to the explorative nature of the single case-study. Generalizability for the study lies on a theoretical level, rather than on an empirical level. This is the case because exploratory case studies are almost impossible to replicate to the fullest [20]. The logic of replication dictates that, for future cases, the use of the same e-service ‘value-in-use’ framework as applied in this study should yield similar results. However, initial results of the exploratory case-study indicate that valuable insight might be gained by the continued investigation into ‘value-in-use’ for implementation research, where the focus is directed towards services for citizens in general. Suggestively, future studies would also include people with different types of digital literacy.
Conclusions

This study explored issues that promote the development and implementation of patient-centered care services for the elderly. It addressed “the lack of awareness and confidence in eHealth solutions among stakeholders”, as identified by the European Commission [1]. This was done by means of an exploratory case study that focused on the ‘value-in-use’ that elderly participants in the AAL Helicopter project experienced while using the piloted service.

Findings indicate that the ‘value-in-use’ concept and specifically the e-Service ‘value-in-use’ framework [14; 19] could give valuable insight for implementing organizations of pre-emptive e-Health services guided towards the elderly.

Developing “Information Assistant”: A Smartphone Application to Meet the Personalized Information Needs of Women with Breast Cancer

Ying Liu⁎, Zhaohui Geng⁎, Fulei Wu⁎, Changrong Yuan⁎

⁎School of Nursing, Second Military Medical University, China

Abstract

Breast cancer presents specific challenges both physically and psychologically to women. Women living with breast cancer frequently do not receive adequate information support and they urgently need professional assistance that help them to cope and adjust to challenges. This paper documents the process of developing a smartphone application (app) “Information Assistant” for women with breast cancer in China. First, individual interviews were used to explore and understand the real experience of breast cancer patients and their diverse information needs during different stages of diagnosis and treatment. Next, expert working group discussions and the Delphi technique, including breast cancer care physicians, nurses and software engineers, were used to draft the structure and contents of the m-health based information support program. Then, these feedbacks were used to develop “Information Assistant” app. This app has five modules: personalized information recommendation, category knowledge center, headline information browsing, newest information browsing and information searching.

Breast Cancer; Information Management; Smartphone

Introduction

Breast cancer is the most common cancer among women worldwide [1-2]. According to the Chinese National Cancer Registry, breast cancer is the most common cancer among urban women and the fourth most common cancer in rural areas [3], cases in China account for 12.2% of all newly diagnosed breast cancers and 9.6% of all deaths from breast cancer worldwide [4].

Women with breast cancer have a higher relative survival rate than other cancers which makes it possible for patients to live a prolonged life [5]. Breast cancer poses specific challenges both physiologically and psychologically to women. A significant proportion of women experienced physical and emotional difficulties within the first year following diagnosis and years later after treatment [6]. Under these circumstances, information support has been identified as being vital to helping women to cope their challenges [7]. Information support not only increases the client’s involvement in the decision-making process which induces greater satisfaction with treatment choices, but also reduces the feeling of uncertainty and helps decrease emotional anxiety [7-9]. Thus, with adequate information support, women could feel empowered to fight their cancer and improve their quality of life [10].

However, the information needs of women with breast cancer have become increasingly difficult to meet as the number of survivors grows and the workforce of breast cancer care physicians and nurses faces personnel shortages. Since there is limited availability of time and resources by clinicians, there is a need to identify a new method to provide adequate information support and improve the quality and efficiency of follow-up care for breast cancer survivors.

Recently, the rapid expansion of health information technology provides such an opportunity. It has been shown that health information technology can play an important role in helping cancer patients to get high-quality information and become active participants in their care [11-12]. Smartphones with variety functionality such as touch screen technology, audio, video, internet access have become a ubiquitous technology in both the developed and developing world [13]. With the increasing usage and acceptance of smartphones, the smartphone applications (apps) have shown great potential to provide clients with information specific to their needs [14].

Our project is to develop a smartphone app to meet the personalized information needs of women with breast cancer in China. The purpose of this paper is to document the process of developing the smartphone app.

Methods

This is a multidisciplinary research program, our research team included three postgraduate students (Ying Liu, Zhaohui Geng and Fulei Wu) majored in Chronic Disease Caring & Cancer Nursing, nursing educationation (Changrong Yuan), breast cancer care physicians, breast cancer caring nurses and software engineers. The research team members worked collaboratively to design and conduct the research. The workflow of the multidisciplinary research and developing of the app is presented in Figure 1.

Data collection spanned from March 2015 to December 2016. First, interviews and follow-up study with 12 breast cancer patients were used to explore and understand the real experience of breast cancer patients and their diverse information needs during different stages of diagnosis and treatment. Next, the expert working group discussion including 7 experts from medical, nursing and software engineering was conducted. Experts added some information need contents of breast cancer patients from their professional point of view, and gave suggestions for developing an m-health based information support program. Then, a Delphi expert consultation was conducted, in which 20 clinical nursing experts participated and gave their opinions on the core part of the mobile information support program. Finally, expert consultations including 5 clinical medical and nursing experts and 3 software engineers were conducted. A researcher organized the multi-disciplinary cooperation of the experts to revise and finalize the mobile information support program, and then work with software engineers to develop the software.

The study was approved by the National Natural Science Foundation of China and the Second Military Medical
First, a qualitative approach was used to collect data about the information needs of women with breast cancer during diagnosis and treatment process. Twelve women who were diagnosed with breast cancer between March to April 2015 were selected to be interviewees. Eligibility for participating in this key informant interview included: (a) participants were diagnosed with breast cancer for first time, and receiving treatments; (b) participants were above 18 years old and they were able to communicate fluently in Chinese; (c) participants knew about their diagnosis and they were willing to talk about it; (d) participants were interested and willing to use smartphone apps to facilitate their breast cancer care. Informed consent was obtained from those participants.

We conducted at least two interviews with each patient and also had a 6 months follow-up to get the whole picture of patients' heterogenous information needs during the different diagnosis and treatment process. The first interview for each woman was conducted during her diagnosis stage before the surgery, and the second interview was conducted about 2-4 days after her surgery. Some patients even had a third time interview just before they discharged from the hospital. The follow-up was started when the patient discharged from the hospital and went to his/her home or community for further rehabilitation, and all follow-up lasted for about 6 months.

All face to face interviews were conducted in conference rooms of several different hospitals in the east provinces of China and each interview lasted for 30-45 mins. The follow-up was conducted by telephone calls, short messages and the WeChat (a communication software).

Topics and questions related to patients' possible information needs were derived from the literature review and physicians' and nurses' clinical experience. During the interviews and follow-up, participants were asked to describe: (a) their perception of breast cancer; (b) their experiences and feelings during breast cancer diagnosis and treatment process; (c) challenges they may face and information needs in living with breast cancer.

The individual interviews were audio-recorded with participants' consent and continued until data saturation was reached, meaning that no new information of value was obtained from the interviewees. Interviews were transcribed verbatim within two days of the interview.

A qualitative content analysis aimed at finding manifest and latent meanings of data was applied to analyze the information manually[15]. Firstly, the transcripts were read several times by the researcher, then segmentation of information was done and significant information related to research questions was extracted. Finally, data were coded and grouped into categories and abstracted into sub-themes and the main theme.

**Groups Discussion Round One: Physicians, Nurses and Software Engineers**

The group discussion with breast cancer care physicians, nurses and software engineers was conducted to draft the structure and contents of the “information assistant” app. The physicians and nurses had at least ten years working experience with breast cancer patients, and they were qualified with a masters degree or above, with the exception of one nurse who was qualified with a bachelor degree.

The discussions were conducted in a conference room at School of Nursing, the Second Military Medical University in China and lasted 120-150 mins. After the first round of group discussion, one-on-one interviews ranging from 20-45 minutes were conducted in a private room with those who were relatively active in the group discussion, to gain more suggestions.

The group discussion focused on: (a) what’s the breast cancer patients’ diverse information needs during the diagnosis and treatment process from health care providers’ point of view; (b) what questions or problems patients consulted most in the follow-up caring of breast cancer; (c) how can health information technology and the app help in meeting patients' information needs and give real-time feedback?; (d) professional suggestions of structure and contents of the app.

**Electronic Mail Delphi Study: Nurses**

In order to identify and gain consensus on items and contents of information knowledge for addition into the app to support patients, and have more professional advice in facilitating the development of the app, we conducted an electronic mail Delphi study. The e-Delphi was more efficient and less time consuming. Nurses from all over China, who were not able to attend a face-to-face consensus conference or take part in nominal groups, were invited to participate in this study.

According to Keeney [16-17], Delphi does not use a random sample which is representative of the target population, rather, it employs ‘experts’ in the area in which the researcher is interested. As for this study, our research team defined and chose nurses who had more than five years working experience with breast cancer patients.

An introduction to the study and specific goals to reach were given to the participants in the first round consulting. The first round questionnaire consisted of two sections: the first section was the demographic information about the experts, including education background and working experiences. The second section was the main part. In this section experts were asked to give their opinions whether to accept or refuse or suggest for
revising about each item within the “eight information banks”. Some open-ended questions also included that experts can add more details on each information bank and give advice on revising the “information assistant” app.

**Group Discussions Round Two: Physicians, Nurses and Software Engineers**

We held the second round group discussion to finalize the “information assistant” app. Five experts in medical and nursing field who had already participated the first round group discussion were included, and the second round discussion also included three engineers. The discussion was conducted in the same conference room as previous and lasted between 120-150 minutes. We presented participants a protocol with revised structure and contents of the “information assistant” app. The discussion was focused on: (a) confirming the structure and main functions of the app; (b) modules, main functions and useful tools of this app; (c) easy to use and user-friendly interface; (d) the web-based administration portal.

**Results**

**Draft the Structure and Contents of the “Information Assistant” App**

**Individual Interviews**

In total, 12 women with breast cancer participated in the interview. The age of the participants ranged from 36 to 67 years, with a medium of 47 years. Half of them had a full-time job, eleven of them were married, and four had an education level above high school. As for their treatment, three of them had surgery only, seven had a combination of surgery and chemotherapy, and two had a combination of surgery and other adjuvant therapy.

Five major categories of information needs are identified as: (a) psychosocial support needs; (b) information about the treatment choosing and planning; (c) surgery process and related adverse reactions; (d) side effects of chemotherapy and coping strategy; (f) instructions of self-care at home. This part was reported in our previous work [18].

**Group Discussion Round 1 and Individual Interviews**

There were one physician (with 15 years working experience with breast cancer patients), five nurses (with an average of 18.8 years working experience with breast cancer patients) and one senior software engineer participated in the discussion.

During the discussion, we developed a draft of information support protocol. First, we provided the expert with the results of the qualitative study of the patients' true information needs, as well as our previous literature review findings in the group discussion.

Next, considering all patients' needs, professionals opinions and the breast cancer treatment guidelines [19], we identified eight key phrases in breast cancer caring, and these key phrases represented eight different stages in breast cancer care (see Table 1).

We assumed that patients in each stage can receive personalized information support through the app. Then we identified the concrete information contents in each stage; a total of 62 information items were identified. We called the overall stages and information items as “eight information banks”, and our next step would be to build the eight information banks.

Besides this, the group discussion also identified three more contents of the app as: (a) a category knowledge centre including all information; (b) a headline information browsing part for patients to get the most helpful information; (c) the newest information browsing part for patients to get the latest information about breast cancer treatment and caring.

**Revise the Structure and Contents of the “Information Assistant” App**

There are 20 (a response rate of 91%) nursing experts participated in the round 1 e-Delphi study and they all completed the round 2 study. They came from five provinces (Shanghai, Zhejiang, Jiangsu, Hubei and Guangdong) and seven Grade III Class A hospitals in China. The age of the participants ranged from 29 to 54 years, with a mean of 38.9 years. The average working time was 17.0 years, ranging from 7 to 36 years. As for the education level, 15 of them had a bachelor degree or above.

The essential objective of this e-Delphi study was to access the suitability of each item and to identify any additional valuable information items in the eight information banks. The overall original items of the eight information banks were 62. After the 2-round e-Delphi process, the experts reached consensus on 84-items information banks. According to the experts' suggestion, we added some useful information items in each bank so as to develop a more helpful app, enabling patients with breast cancer to get the maximum benefit.

The process of identifying information items during the 2-round Delphi study is shown in Table 1, and in Table 2 we present the contents of “adjuvant chemotherapy stage” as one example of the eight information banks.

**Finalize the “Information Assistant”**

In group discussion round 2, we went through our previous results, revised our contents and structure about the app and then finalized the app.

We did some modification of the app, for example, experts suggested that a searching bottom should be added to the interface of the app, to make it more user-friendly and easy use. Since most of our information support items were text materials, it may be difficult for some patients to catch up the
meaning. To facilitate the patients’ understanding we added photo and video materials in the eight information banks, e.g., for breast self-examination and post-operation exercise. Finally, an app with five main function modules was developed, as presented below:

**Module One: Personalized Information Recommendation**
This module is the major function of the app. In this module, we match the patients’ present medical status, treatment planning and information preference with the “eight information banks”. Based on this, we analyze and extract relevant information items from the bank, and then we deliver personalized information support to the patients.

**Module Two: Category Knowledge Center**
This module presents all the credible information that patients may want to know about breast cancer caring, including diagnosis, different tests, treatment regimens, medication management, dietary and nutrition instruction, and rehabilitation exercises instruction. Patients can find useful information in this module as complementary to the personalized information recommendation.

**Module Three: Headline Information Browsing**
This module is to provide the headline information which patients browse most. Patients best know what they want to learn. The top ten information items identified by real-time page views through our web-based administration portal could best represent issues that patients are concerned with.

**Module Four: Newest Information Browsing**
Both personalized information recommendation module and category knowledge center modules are based on the fixed eight information banks. This module is reserved to display latest research findings, new technologies and new methods about breast cancer caring, thereby helping patients get the most updated information.

**Module Five: Information Searching**
This module is also complementary to the personalized information recommendation. Patients who may have problems to find the information they need can search in this module. Just like searching in google, patients can search by typing in the keywords and all credible information related within the eight information banks will be displayed on the screen.

Two screenshots are given as examples to visualize the smartphone app in Appendix (labeled as Appendix Figure 1 and Appendix Figure 2). The software is in the debugging process currently, the practical application and effectiveness test of the software will be carried out in our future study.

**Discussion**
Hearing of the diagnosis of breast cancer or just suspected of breast cancer, can put heavy pressure on patients, let alone enormous challenges they may face related to the various of treatments or rehabilitation strategies. Information support plays a vital role in helping patients to cope with their condition, as proved in many studies [7-10], and the effectiveness of web-based information systems has also been reported [20-21]. So, our focus in this work was not whether the information support would be useful for breast cancer patients, but how to adopt a more efficient and effective way to provide them with optimal information support. Inspired by the idea of m-health [13], a smartphone app which has huge advantages over the traditional ways [22] was developed based on a scientific method. The primary goal of this “information assistant” is to meet the personalized information need of breast cancer patients, and provide each patient with personalized information support according to their different medical status, treatment process and special needs. Based on interviews with breast cancer patients, group discussion with physicians, nurses and engineers, and e-Delphi study, the protocol of this “information assistant” app was developed. A qualitative study is a credible way to explore patients’ true needs, and an e-Delphi study is an efficient way to gain consensus by experts. Besides, multidisciplinary group discussion promotes better communication and understanding between experts. These all contribute a lot to develop the app and deliver high-quality information support for the patients.

There were also some limitations of this study; first of all, the participating patients in interviews and experts in group discussions were relatively few and the findings may not cover all patients’ information needs in various conditions; secondly, although e-health technologies have thrived in health care industry, there is no guideline or generally accepted principles for our health provider to develop a smartphone app. Finally, future research is needed to examine the usability and effectiveness of the “information assistant” app, and to optimize the app accordingly.

**Conclusion**
In this study, we tried a new method (smartphone app) to provide personalized information support for patients with breast cancer. By combining the results with patients’ interviews, experts group discussion, and e-Delphi studies, we developed the “eight information banks” and developed the “information assistant” app. This app has five modules; personalized information recommendation, category knowledge center, headline information browsing, newest information browsing and information searching. Each module has a unique function to support patients optimally. Meanwhile, this process also gives a good example for future studies focusing on the design of e-health smartphone apps.

Abstract

This study aimed at developing an assessment of smartphone usage competence and constructing a training program for the elderly. A list of smartphone usage competencies with 34 items was defined through expert survey and panel. Based on the competency and previous literature, a training program and learning aids were designed in this study. There were 41 participants in our program. The results of self-administrated smartphone usage ability questionnaire indicated that all competencies were significantly improved after training. However, the results also demonstrated that some items were still difficult for the elderly to comprehend. Overall, this study provided a first exploration of defining smartphone usage competency and built a training program for the elderly. With strong suggestion, future mobile health (mHealth) services can follow this study to insure the smartphone usage ability of the elderly.

Keywords:
Aged, Education, Smartphone

Introduction

Noncommunicable diseases (NCDs) have become the leading cause of death around the world and caused 38 million deaths in 2012 [1]. Furthermore, higher prevalence of NCDs among older adults has been reported [2]. Due to irreversibility of NCDs, slowing down the process of the diseases and keeping healthy lifestyle have become the main targets of treatment. Under this situation, technology tools became important assistants for controlling the chronic diseases.

Mobile health (mHealth) represents a subset of telehealth. On account of rapid progress in mobile technology and widespread wireless network, mHealth became a novel model of health care service. Since the smartphone appeared, it has been quickly accepted by all ages around the world. Multisensory, wireless transmission and powerful computing power make smartphones a major mHealth device, and many smartphone-based health care services and research projects are ongoing [3,4].

Nevertheless, according to Aaron Smith’s report, the smartphone adoption rate is relatively low in the aging population [5]. Many factors were identified as barriers for older adults to use smartphone, including decline of cognition, reduction of hand motor control, tardiness of information processing, and limited attention[7,8]. Furthermore, the elderly are rarely the main target of technology applications [9,10]. All above reasons are responsible for the lower smartphone adoption rate among the elderly.

In contrast, several researches have indicated that the obstacle of using smartphones for the elderly is not aging process or decline of learning ability but lack of proper training. If seniors can be provided with suitable training, they can develop greater ability of using information technologies and increase their willingness to use [9]. Therefore, the first task of serving the elderly with mHealth service is smartphone training programs.

Competency-based learning has been widely applied to design of training programs for workplace newcomers, medical students, as well as informatics literacy education [11]. The core value of competency-based learning is task-specific. Only highly task-related competence should be involved and all content of training program should base on the competence. Because the elderly do not need to be familiar with all functions and knowledge of the smartphone, the features of competency-based learning make it a strategy for developing training program.

Thus, the objectives of this study are: 1) define the essential smartphone usage competency for the elderly and 2) established a competency-based smartphone usage assessment and training program for the elderly.

Methods

The research divided into three parts: 1) define smartphone usage competence, 2) develop a smartphone usage training program and learning aids, and 3) apply the training program and evaluate the outcomes.

Define smartphone usage competence

Online expert surveys were applied to build the initial competencies. The questionnaire was designed with two open-ended questions to investigate what functions and knowledge of smartphones are needed for the elderly in mHealth. There were five experts surveyed, including three senior researchers in mHealth and two mobile application programmers. All functions and knowledge from the expert survey were analyzed by the research team and listed out to make up the initial smartphone usage competence for the elderly.

To validate the competencies, three senior researchers in health science of aging populations and one scholar who is a master in mobile healthcare system engineering were invited to constitute an expert panel. In the panel, each item of the initial smartphone usage competencies was reviewed for validity and readability. According to experts’ opinions, smartphone usage competencies were proposed and used in constructing the smartphone usage training program for the elderly.
Develop smartphone usage training program and learning aids

Based on the competencies developed in previous stages, a smartphone usage training program was constructed for older adults. Each item in the competence list was put into the program. Acknowledging previous studies, our program follows four principles as stated below [10,12]:

- Include essential context
- Manage with task and scenario practice orientations
- Arrange the course according to the relations between each unit
- Design for levels ranging from easy to hard

The learning preferences of seniors were considered. The training strategy followed the principles as described below [6,12,13]:

- Allow learners with time to practice in the class
- Avoid using technical terms in the lecture
- The interval between sessions should not be long
- Provide several class dates for the elderly to choose

The learning aids were also designed following the suggestions of previous research. Previous studies have several recommendations for mobile phone instructions for seniors, such as [14]:

- Provide pictorial instructions, using words for aid
- Maximize the figures and words
- Make sure all contents are covered in the instructions
- Allocate all controls that will be used
- Start from the same view and never miss a step

Apply the training program and evaluate outcomes

We recruited a convenience sample of older adults from a metropolitan hospital in Taipei, Taiwan. We posted the information for our study and accepted applications from interested participants. Prospective participants were eligible to participate in the study if he/she was: more than 50 years old, and not hospitalized. All prospective participants were informed of the research procedure before recruited.

After being recruited, all participants completed a questionnaire that inquired about their demographic information (e.g. age, gender, education background, career) and their smartphone usage ability. The smartphone usage ability questionnaire was based on our smartphone usage competence and used a 5-point Likert scales to evaluate each item in the competence list. A competence score of 5 represented excellent competence, and 1 represented very poor competence. Next, each participant received an android phone and learning aids. All participants were asked to complete the whole training program. We offered 2 different time slot for each class, and all participants were asked to attend each class for one time. After all courses had completed, the elderly were required to self report their smartphone usage ability by the same questionnaire as beginning. The pre-test and post-test score were analyzed as the outcome of our training program. This study was approved by the Taipei City Hospital Institutional Review Board.

Results

The smartphone usage competency

There are ten smartphone functions and seven smartphone concepts that were proposed by the experts. The common reported-functions were calling (n=4), accessing internet (n=4), and system preferences setting (n=4). Other essential smartphone functions included SMS messaging (n=3), switching the phone into on, off, or standby modes (n=2), download applications from Google Play or other platforms (n=2), manage contacts (n=1), switching GPS on or off (n=1), and operating the touch keyboard (n=1). The frequently reported knowledge of smartphones included meanings of gestures (n=3), concept of network data flow (n=2), awareness of smartphone applications (n=2), conceptual understanding of the smartphone exterior and the position and function of each button (n=2), the difference between 3G and Wi-Fi (n=1), the meanings of icons on the notify bar (n=1), and conceptual understanding of the android home screen (n=1). By analyzing and organizing the sub-functions and related knowledge of 17 items, we listed out 41 core competencies of smartphone usage.

An expert panel was conducted to validate the smartphone usage competence. The suggestions of experts were 1) divide some items that contain two concepts or functions, 2) combine some similar items into a single item, 3) eliminate redundant items, 4) and simply and clarify the description of items to make it plain for the elderly. Besides, experts recommended that application downloaded through a text message should be added into the list. Referring these suggestions, 34 items were included in the final competence of smartphone usage and categorized in 7 groups (Table 1).

Smartphone usage training program

Based on the competencies, a smartphone usage training course and a series of learning aids were developed. The training course contained 12 units to cover all smartphone usage competencies. In order to shorten the course time, the course was separated into two classes and each class was no longer than 1 hour. The sequential order of the content in each class were based on the difficulty in each unit. Therefore, the first class began with introducing the fundamental knowledge and functions of smartphone, containing 1) introducing the appearance of smartphone and how to install the SIM card and battery, 2) switch smartphone to on, off, or standby modes, 3) turn the volume up or down, 4) answer and make a phone call, 5) maintain the address book, 6) send and receive SMS messages, 7) manage the home screen, 8) and take a photo and record video. The second class was more advanced. The topics were: 1) switch 3G, Wi-Fi and GPS on or off, 2) introduce the concept of network data flow, 3) introduce Google Play and how to download an app, 4) and download applications from a SMS message. All participants must attend each class and finished all courses in two weeks. The classes were lecture-based and the lecturer performed each of function step-by-step with the participants. After the demonstration, plenty of scenarios were given to participants and all participants were required successfully solve problems in these scenarios.

Smartphone usage learning aids

The learning aids contained two parts: a learning instruction with colorful comic strip (Figure 1) and a text-based manual booklet. The colorful instruction included all smartphone functions that were introduced in our training program. All functions were shown step by step and all essential controllers were pointed out on the instructions. In order to make the
instructions easier to read for older adults, the features of instruction were listed as follows: 1) all functions start from the same screen, 2) mainly show using pictures and assist with simple sentence, and 3) text size was 16px and pictures were as big as the smartphone used in this study.

Second, the text-based manual booklet focused on introducing the essential knowledge of using the smartphone (e.g. the functions of physical buttons, the meanings of icons, the concept of home screen, and concept of a network). Since the concepts were hard present by picture, the manual booklet mainly consisted of 14px text.

Table 1 - Smartphone usage competencies

| Items | |
|-------| |
| 1. Fundamental knowledge of smartphone system | |
| 1.1 Install SIM card and Battery | |
| 1.2 Switch on the smartphone | |
| 1.3 Turn smartphone into standby mode | |
| 1.4 Wake smartphone from standby mode | |
| 1.5 Know when the battery need to be charged | |
| 1.6 Know how to charge the battery | |
| 1.7 Know the meanings of touch, press and hold, and drag when using the smartphone | |
| 1.8 Know the position and function of power, volume, menu, home and back button. | |
| 1.9 Know the position and function of microphone, speaker, back camera, and USB slot. | |
| 1.10 Know the meaning of icons (e.g. status of internet, battery, GPS, and reception) on the notify bar | |
| 1.11 Know the meanings of Standby, GPS, Google Play, and Wi-Fi | |
| 1.12 Able to discern buttons and text fields | |
| 1.13 Able to turn the volume up and down | |
| 1.14 Able to use touch keyboard to input data | |
| 2. Calling | |
| 2.1 Able to enter the phone number and make a call | |
| 2.2 Able to find a contact person from the address book and make a call | |
| 2.3 Able to make a call from communication records | |
| 2.4 Able to answer or hang up the phone | |
| 3. SMS messaging | |
| 3.1 Able to send and receive a short message | |
| 3.2 Able to download a application from a short message | |
| 4. Contact management | |
| 4.1 Able to add a new contact | |
| 4.2 Able to maintain contact information | |
| 4.3 Able to delete a contact | |
| 5. Take photo and record video | |
| 5.1 Able to take a photograph | |
| 5.2 Able to record a video | |
| 5.3 Able to browse the photo and video on the smartphone | |
| 5.4 Able to delete the photo and video | |
| 6. Manage home screen | |
| 6.1 Able to create and remove a shortcut of application | |
| 6.2 Able to create and remove a widget | |
| 6.3 Able to operate the widgets | |
| 7. Access internet and download applications | |
| 7.1 Able to switch the 3G wireless on and off | |
| 7.2 Able to search and download applications in Google Play | |
| 7.3 Able to switch GPS on and off | |
| 7.4 Know the meanings of network data flow | |

Figure 1 - Colored comic strip learning instruction

Implementation and evaluation of the smartphone usage training program

A total of 49 subjects participated in the study during July 2012 to November 2012, and 41 subjects completed the training program and self-reported questionnaire of smartphone usage ability. The age of participants were mostly between 60 to 69 years (65.9%), and were 39% male and 61% female. Participants reported variation of smartphone usage experience: 60.5% had not used smartphone, 12.2% had used smartphone less than one year, 19.5% had 1-3 years of smartphone experience, 2.4% had 3-5 years of smartphone experience, and 10.5% did not reply the question. The characteristics of the subjects and their previous experience of using smartphones is demonstrated in Table 2.

Pretest of smartphone usage ability

Overall results are shown in Table 3. The average pre-test score of smartphone usage ability was 1.91±1.39. Most participants evaluated themselves with poor or very poor in using smartphone. Participants reported higher score in calling (2.18±1.67), contact management (2.05±1.54), and fundamental knowledge of the smartphone (2.02±1.47). In contrast, accessing the Internet and downloading applications (1.54±1.08), managing the home screen (1.68±1.18), and SMS messaging (1.91±1.34) were reported with lower score.

Post-test of smartphone usage ability

After training, the average score of smartphone usage ability among participants was 3.16±1.00. Participants were inclined to score their smartphone usage as average or good. Calling, fundamental knowledge of the smartphone, and contact management were still evaluated with higher score (3.70±0.87, 3.64±0.74, 3.15±1.08). Manage the home screen, accessing the Internet and downloading applications, and SMS messaging were relatively lower (2.76±1.10, 2.90±0.96, 2.89±1.12). Comparing to the pre-test scores, all scores significantly raised (P<0.001).

Discussion

Our study proposed a list of smartphone usage competencies and a training program to promote smartphone usage abilities of the elderly. Previous research has focused on training strategies, learning outcomes, and technology usage pattern of older adults [10, 15, 16]. Few studies, however, have emphasized the content of training programs and its advantages for elderly to receive mobile health care services. To our knowledge, our study is the first to investigate the smartphone usage competency needs and build a competency assessment, as well as training model for the elderly by ascertaining expert opinions.

The prerequisite for the elderly to participate in mHealth services is smartphone usage ability. The benefits of the services will be greater when seniors can master with all smartphone functions used in a certain service. Our smartphone usage competencies contain all functions that were frequently utilized in mobile health care services. According to the report by Free et al. (2013), calling, SMS massaging, GPS tracking, and downloading applications were the most widely used functions in mHealth services [4]. This demonstrates that our smartphone usage competencies can significantly match the needs required for mHealth services.

The contents of our smartphone usage training program were based on our smartphone usage competency. Therefore, it can be confirmed that well-designed programs can promote smartphone usage ability among the elderly. However, our program did not consider what the elderly is actually interested in. They are particularly interested in social applications include Line, Facebook and other entertainment applications. Although their needs may have no relation with the mHealth service, some previous studies have demonstrated that it will increase the motivation for adopting and learning among seniors when the technology fits their needs [17]. Thus, it is advised to moderately involve applications that interest the elderly, because these applications will motivate them to learn.

Our smartphone usage ability pre-test data show that most older adults evaluate their smartphone usage ability as poor or very poor. This finding is consistent with past research, which states that older adults often grade them self with low self-efficacy of technology use [6, 18]. It also shows that the importance of smartphone usage training for the elderly before receiving the mHealth services.

After training program, post-test data illustrates that the usage ability of all functions included in our competence list were significantly improved. This finding provides with the insight that our training program and learning aids can positively promote the smartphone usage of older adults. Our findings also indicate that older adults still have ability to learn technologies, and this outcome is consistent with several previous reports [10, 15, 16].

Results also demonstrate that some specific functions and knowledge still are difficult for older adults to understand after training. Managing the home screen, accessing the Internet and downloading applications, and SMS messaging were the functions that were reported with lower scores. The possible explanation of the result could be an unfriendly interface design for the elderly. Although many studies have been started to give priority to interface design for the elderly, a senior friendly smartphone has not yet been produced [9]. Moreover, it is hard for the elderly to comprehend the concept of specific functions and knowledge because they have not had prior experience. Therefore, our study suggests that future programs for smartphone usage training among older adults should put more efforts on these functions and concepts.

There are several limitations needed to be considered in our study. Since our participants were convenience samples selected from a metropolitan hospital in Taipei, Taiwan, the majority of them live in the same region. The demographic features (i.e., education, economy, health status, and technology experience) of our samples may be dissimilar from older adults who live in another region. This aspect may limit our findings’ generalizability. Additionally, it is difficult to highlight that all improvements of smartphone usage ability among the subjects were due to our training program since our study did not include a comparison group. Finally, past studies have indicated that a small class is better for the elderly [10]. However, under the consideration of teaching consistency and research resources, large classes (maximum 20 participants at once) were conducted for our study. The effect of class size on our outcome of training program was not examined.

Conclusion

Our study defines smartphone usage competencies for older adults and applies the competency-based learning as a strategy to build a smartphone usage training program. According to expert suggestions, our smartphone usage competencies cover all functions that have been frequently utilized in mobile health care services. The result of smartphone usage ability reported among our participants indicates that our training program can significantly improve the smartphone usage ability for older adults. With the ability to use a smartphone, the elderly can collect the health parameters through the smartphone and ensure the reliability of the data. We suggest that future smartphone-based health care services or studies can make reference to our research to make sure the data collected from the elderly are meaningful.

Abstract

Health Smart Homes provide various forms of assisted living support, by monitoring the activities and health status of their occupants to generate flows of information and sometimes interventions involving the occupants and their careers. Technologies of varying complexity must be combined to produce the underlying Health Smart Home system, and processing of the resulting data may require methods of varying sophistication. These aspects have been well studied, but no widely-adopted approaches for practical implementation of systems or systematic processing of data have been developed. Also, the integration of Health Smart Home services with the overall health care system has not been regularized. This paper identifies and categorizes the emerging high-level challenges beyond those in the basic technical and algorithmic spaces. These challenges will influence future directions for Health Smart Homes and their wider adoption and integration with health systems.

Keywords: Assisted Living Facilities; Computing Methodologies.

Introduction

Contemporary Smart Home concepts have been developed over the last two decades. A Smart Home consists of a living space equipped with electronic devices and communications infrastructure to enable monitoring and control of the immediate physical environment, coupled with a system with sufficient computational power, data storage and decision making capabilities to provide customization and efficiency of operation [1]. The emergence of Wireless Sensor Networks [2] and more recently, the Internet of Things (IoT) [3] and Cloud Computing [4] services, have provided the ideal technical fabric for constructing Smart Homes. Integration approaches relying on middleware and open source conversion platforms for various device and communications standards are now being supplanted by evolving Cloud-IoT synergies [5].

Health Smart Homes have been popularized alongside the mainstream Smart Home movement [6], with additional distinctive characteristics. Their purpose is more critical, in that they must measure, understand, and manage the health status of their occupants [7]. Early technical challenges identified for Health Smart Homes included the lack of appropriate sensor availability and performance [8], and difficulty in coordination of subsystems to provide component functions targeted to health needs [9]. The importance of social and ethical considerations for home occupants and subjects of care were also identified [10], and the need for multidisciplinary collaboration in the development of more comprehensive health solutions [11]. Examination of Health Smart Home experimental implementations has revealed a wide spread of technology choices across numerous contexts [12], but little evaluation of their clinical effectiveness has been performed [13]. Despite attempts to standardize health sensor device protocols, such as the Continua framework [14], the lack of integration at a systems level remains a major limitation [15].

More recently, emphasis is being placed within health systems in the development of new models of care where consumers can receive a range of health services in new settings including their homes [16]. There is a clear consumer-supported move towards the widespread use of personal monitoring devices [17] that will need to be integrated into this emerging care environment. There is also a more general societal move towards wider access and use of personal electronic health records, and the implied connectivity of information systems, which will be required to achieve this [18]. Increasingly, interoperability and standardization are becoming aspirations for health systems that will ultimately rely on universal electronic data exchange and rich information environments supporting personalized “precision” patient care [19]. Health Smart Homes will need to harmonize with developments in these areas and, importantly, become part of a health services continuum, rather than isolated entities.

Methods

Given this broader perspective, we can readily distinguish two major challenge areas, Systems and Data, that will need to be addressed in the Health Smart Home of the future. In the following sections, we identify aspects within these two areas that are currently open issues and for which substantial work is needed to make further progress.

Systems Challenges

In the context of whole-of-systems concepts for Health Smart Homes, we comment on three new challenge areas: Architecture issues, including overall design considerations; Integration issues, such as interfacing and interoperability; and Safety issues, involving protection of users and the systems themselves.

Architecture Issues: The computing-based components consisting of: (i) hardware units; (ii) connecting networks; and (iii) intelligent software modules, which make up a Health Smart Home, can be viewed as a Critical System, in the same sense as large scale physical infrastructure systems (e.g., power grid) or complex machinery control systems (e.g., passenger aircraft). Such systems need mechanisms to allow update and replacement of components without disrupting system function, and addition or deletion of components without compromising
the integrity and performance of the system. This would imply an ability to assure the effects of any such changes, and to predict their impact, on other components should be embedded in the system development methodology [20]. Consistency of protocols for managing data and control within critical systems, including movement towards self-validation to provide error resilience to changes [21] along with convergence of Wireless Sensor Networks with IoT and Cloud Computing technologies [22], will help advance this cause.

**Integration Issues:** To achieve fuller knowledge of past health history and to conduct longer time frame modeling of occupants’ complex health circumstances (e.g., when monitoring a subject with multiple chronic diseases), it may be necessary to connect with external sources of health information on the individual and leverage sophisticated external health decision making and services delivery systems. This implies interoperation of the Health Smart Home with other health services will be necessary, which in turn will have associated impacts on workflows and care models. Some reconceptualization of the Health Smart Home as one of the essential components in the overall health system would help to address this matter. This would include differentiating between the role of supporting healthy living (e.g., preventive health coaching and lifestyle monitoring) [23] and that of supporting existing acute health care delivery (e.g., the numerous “hospital in the home” initiatives) [24]. Monitoring to support acute care at home is currently arguably more socially acceptable and the intrusiveness of the required technology tolerated if not accepted. However, in designing for non-acute care and supporting everyday wellbeing, this level of acceptance and related engagement diminishes [25].

**Safety Issues:** As wireless connectivity becomes ubiquitous individuals are placed at higher risk of accidental or malicious interference with electronically managed data streams and control functions. This security vulnerability is amplified in high density Wireless Sensor Networks and IoT settings [26] such as Smart Homes, and where the sensitivity of health data to breach must be considered. Protection against such situations necessitates rigorous enforcement of failure detection and recovery, audits and monitoring to determine misuse, and system risk management processes to mitigate against failures. Robustness and resilience components in the system design cycle need to be developed, and operational surveillance protocols need to be established so that warnings can be generated and fail-safe defaults adopted. Whether it is in the pre-determined sensor networks or the healthcare IoT environment, the fail-safe modes of devices, such as power failure incidents, must be carefully considered. The fail modes - default on or default off – need to be contextually considered. For example, under some conditions in falls monitoring, a false negative (e.g., from a slow fall) may be more damaging than a false positive (e.g., bending down to reach the floor). Further, the device susceptibility to attacks and the challenge of applying traditional security models with delineated network boundaries to dynamic Smart Home and Healthcare IoT networks, pose significant problems which demand more attention in system standards development [27].

**Data Challenges**

Extracting more value from health data is currently a major emphasis in formulating major electronic health record and Clinical Decision Support strategies. This is beginning to extend to the use of data from sources such as Health Smart Homes monitoring. Three aspects of this trend contribute to the emergence of new issues here: Management of the related data-sets including content and custodial issues; Recognition of relevant patterns in the data to allow accurate continuous classification of an individual’s activities; and Personalization of decision making concerning health events or status, relative to the individual’s aggregated data.

**Data Management Issues:** As in hospital-based patient record systems, strict establishment and adherence to standards for Health Smart Home datasets will be necessary, and equally, the interpretation of externally sourced health data on individuals will need to be informed by knowledge of those standards. Little existing standards work has been reported for Health Smart Home settings and this inhibits wider use and sharing of datasets with other elements in established health systems. If this was addressed it would become easier to provide reference sets of experimental data for algorithm tuning and benchmark data for performance analysis. In the same way as standards were adopted in the research community for sharing physiological datasets via PhysioNet [28], a similar practice would be desirable for Health Smart Homes where sharing is much less common [29]. Another related matter is that of the processing of the data in a Health Smart Home to ensure clinical usefulness as well as appropriate detection and response to potential health indicators. The healthcare workflow and the integration of data from sensors with clinical knowledge is of vital importance to assure improved health outcomes [30].

**Pattern Recognition Issues:** Characterization and reliably detecting patterns associated with health conditions (e.g., using physiological signals) or behavioral manifestations (e.g., mobility tracking) remains an open problem. Much effort has been invested in attempts to create robust algorithms for such pattern extraction using machine learning and artificial intelligence methods on data which may be sparser than desired due to physical limitations in the collecting infrastructure [31]. The highly variable nature of repeated situations and activities, both between and within subject, and allowing for “drift” in patterns over time and in different contexts can confound the success of these approaches [32]. Statistical detection of anomalies and structuring patterns into a hierarchy of macro to micro pattern characterizations offer some positive directions for longer term adaptation within activity algorithms, leading to greater consistency of results [33]. The enormity of the range and tolerance issues associated with achieving high sensitivity and specificity performance for detecting and classifying daily living activities, will likely maintain this challenge for research into the foreseeable future.

**Subject Personalization Issues:** Personalized application of algorithms in a Health Smart Home is an essential feature of its operation: if real health benefits are to be gained then it is necessary to tune the system as well as possible to fit the characteristics of the occupying individuals. This may require considerable sophistication in classifier decision-making logic, as well as dealing with multilayer redundancy through the existence of overlapping data sources (e.g., wearables vs ambient) in the data collection and processing stages [34]. Interference from interactions with other people and from externally imposed events which affect the individual, can degrade performance considerably. The more factual data that can be collected on an individual, and the more information that captures the influence of context and current situation, the more opportunity there is to create a fuller personalized picture [35]. Incorporating knowledge of phenotypical habits such as a weekly cycle of behavioral interactions and incorporation of indirectly measurable affective parameters such as mood and stress, may also contribute to overcoming these limitations [36].

---

A.J. Maeder and P.A.H. Williams / Health Smart Homes: New Challenges 167
Discussion

The simplicity of typical Health Smart Home solutions and the lack of compelling evidence for their clinical effectiveness has been identified as a major limitation in their adoption [37]. On the other hand, the increasing importance of home-based healthcare delivery and the consequent acceleration in the need for Health Smart Homes has been noted [38]. The clinical evidence for keeping people at home and avoiding unnecessary hospital admissions is plentiful [39]. Integrating social and health care, patient self-management, socio-economic status as well as coordination with primary care providers are some of the factors that can impact this [40]. The use of Health Smart Homes could be a vital component for improvement in keeping people at home longer.

It is probably unreasonable to expect that any of the new challenges identified above will be resolved by incremental progress, or by awaiting an unforeseen breakthrough followed by widespread adoption. The history of Smart Home development has been marked by independent engineering contributions and implementation models driven in a bottom-up manner [41]. A much broader, overarching approach will be needed to catalyze progress in these areas, as they will affect other aspects of the technology. For example, if a standard were to be agreed for data captured by sensors in a Health Smart Home, which prescribed that side information on precision and reliability must be included, then much previous work would be rendered obsolete.

Conclusions

The evolution of Health Smart Homes to achieve widespread presence requires more than technology advancement. The challenges identified above are subtle and complex consequences of the broader environment for health care within which the Health Smart Home functions. However, it seems likely that these challenges will influence future directions in Health Smart Homes, their wider adoption, and their integration with existing health systems. We advocate that more attention should be paid to these broader issues and that related research questions must be explored, alongside the current proliferation of underpinning engineering and implementation work.

Abstract

Cooperative healthcare is regarded as one of the major goals for providing adequate health related information to physicians. To achieve this goal, national authorities and large hospital organizations are introducing large scale, standard based transactional EHR systems. Those systems record and distribute a significant amount of medical related data. This raises the concern of information overload for the intended users. The objective is to elaborate on an architecture and consequently a workflow that allows the generation of an automatic patient summary in a standard based IHE XDS environment. A literature review evaluating the current state of research is conducted. Current eHealth projects, laws and technical background are analyzed. An architecture is suggested, prototyped and compared using SAAM (Software Architecture Analysis Method) against alternative approaches. A technical workflow built on IHE XDR and HL7 FHIR observations is suggested introducing two new services within an IHE XDS product for extracting observations from CDA documents and storing the data on domain level scope. The information is published as an OnDemand Document in the IHE XDS infrastructure.

Keywords:
Electronic Health Record, Information Management

Introduction

For information systems and software products operating in the professional domain of eHealth, one major goal is providing health related information to physicians and patients adequately and timely [1]. Providing medical practitioners with comprehensive electronic health records (EHRs) and information is intended to contribute to an optimized treatment process and essentially improve continuity of care [2]. Therefore, this is seen as a prerequisite to a more efficient and cooperative healthcare [3]. The definition and quality aspects of EHR systems have been evaluated and published according to several approaches over the last years [4]. Subsequently, national states as well as the EU are focusing on introducing regional/national and connected EHRs [5; 6]. As a current example, Austria introduced ELGA “Elektronische Gesundheitsakte” (ELGA) [7]. It is a nationwide, standards-based EHR infrastructure which went online officially in December of 2015. ELGA is regarded as a virtual EHR system for all Austrian citizens connecting all hospitals and a patient portal in several phases [5]. Due to their nature, such large scale EHR systems are expected to record and distribute more medical information and reports than conventional electronic medical records (EMRs) in isolated data silos. Benefiting from this vast information overflow is a challenge for physicians and systems [8]. However, doctors’ acceptance of EHR systems is one major, critical success factor [9]. Presenting the patient’s vital information in a summarized view, extracted from the information stored in the EHR, could lead to a reduction in workload and an improvement in quality of care [10].

This set of data is referred to as a patient summary, a standardized set of medical data including facts that are necessary for a safe and efficient patient treatment. On a European level the epSOS project outlined a special form of such a patient summary [11]. This electronic patient summary is referred to as a “Consolidated Continuity of Care” (C-CDA) document. It has been defined by HL7 and required by the US-driven “Meaningful Use Stage 2” in the HITECH Act [12]. The objective of this paper is to elaborate on and conceptualize the ELGA implementation as an architectural validation of implemented IHE profiles to generate automatic patient summaries. The suggested approach respects currently established interoperability standards and workflows of large-scale EHR systems.

Methods

Focusing on recent work, a literature review of research on the extraction of data and creation of patient summaries was conducted. The research supporting this paper focused on recent publications found in Pubmed and the ACM Digital Library. Only documents published after 2003 were considered. For the identification of relevant papers, the following keywords and combinations were used: “ehr data summary”, “ehr data extraction”, “cda data extraction”, “cda patient summary” “clinical document data extraction”. Relevant references from already included papers were also included. In addition to the analysis of relevant academic papers, current market leading standardization organizations and the technologies of current eHealth projects were identified. National data privacy and health telematics laws as a basis of regional/national EHRs [13] and the technical background of the implemented architectures were analyzed. The newest developments from the standardization units and organizations, whose technology and standard definitions were identified as being used in current eHealth projects, were analyzed.

Using this information, a technical concept intended to seamlessly integrate into a standardized eHealth architecture was developed. In order to validate the feasibility of the concept, a prototype was implemented and integrated into a demo installation of a major eHealth EHR product (sense® by ITH icoserve GmbH, a Siemens company). The product was selected because it is deployed in major parts of the Austrian
ELGA EHR and thus fulfills all requirements defined for the national project [7].

As a final step the architecture was compared with two other approaches discovered in the literature review executed in the initial step. The Software Architecture Analysis Method (SAAM) [14] was used for comparison. The compared architectures are described in [15] and [16].

Results

The following set of standards and technologies were identified as crucial:

- IHE IT Infrastructure Framework (IHE XDS, XDS-I, PIXPDQ, XDR, ATNA and related profiles)
- HL7 Clinical Document Architecture (HL7 CDA)
- HL7 V2, V3 and Fhir as Data- and Communication Model
- Logical Observation Identifiers Names and Codes (LOINC)

The literature review also confirmed the initial assumption concerning the need of a summarization of patient information stored in an EHR infrastructure. Electronic medical records (EMR) and EHR systems still primarily operate on the basis of documents as atomic information entities [17]. For users, this is in strong contrast to the requirements for the EHR to grant fast access to discrete data [18] as well as an adequate and scalable retrieval of information [19]. As the patient summary is intended to be part of an EHR system, this requirement is also mandatory for the proposed architecture. Another aspect is that EHR systems are required to strictly enforce a tight and well defined access control system limiting the user’s rights and abilities. This also impacts the data included in a patient summary since users with different rights may have access to different data presented in the summary. The contained data is also dependent on the treatment context in which the user is accessing the EHR. We concluded that it is necessary to generate a patient summary on demand. In order to fulfill the previously mentioned requirement of the access performance, we suggest a system that uses a database of previously extracted information. This database is populated in the workflow of registering documents in the distributed infrastructure such as defined by IHE XDS [17].

In such an environment the registration workflow is executed by three services implementing the following IHE profiles: Document Source, XDS Repository and XDS Registry, as depicted in Figure 1. The system by definition does not analyze the documents content, the nature of the documents is reflected by the document metadata.

The main task of the OES is to extract data from the CDA documents intended to be registered in the EHR system. To assure standard based communication it is expected to provide an IHE XDR Recipient compliant interface [17], accepting the ITI-41 (Provide and Register Document Set-b) transaction. Using this interface, a standards based XDS Source can submit the data triggering a second ITI-41 transaction to the OES in addition to registering it in the infrastructure. Medical information is expected to be represented in a structured and coded format within the CDA documents, e.g. in the context of the Austrian national EHR ELGA data is coded using the LOINC (Logical Observation Identifiers Names and Codes) Standard. LOINC is a database which provides a universal code system for reporting laboratory and other clinical observations [20]. Using this information, the OES can extract discrete data. To make the data available to all authorized users and systems accessing the affinity domain the data is submitted to the OBS using a REST based HL7 FHIR transaction [21]. The OBS is intended to collect discrete data of the patient. These include, but are not limited to, the data extracted from the previously extracted documents. It is also possible, using the HL7 FHIR transactions to submit directly the discrete values that were collected in the process of progress monitoring of a patient, laboratory data, vital signs from home monitoring, or other [21]. For publishing the data to the affinity domain, the OBS registers an On-Demand Document to the affinity domain using the IHE Transaction ITI-61 [22]. This document, which is assembled at the time of access using the data registered in the OBS service, allows XDS based clients to retrieve the data wrapped in a CDA L3 document using the standard ITI-43. In addition, it is also possible to access the data using an HL7 Observations Query, if the client wants to avoid processing an XML based documents (e.g. on mobile devices, where REST based API calls are preferred [23]). The workflow of the registering and retrieval process is outlined in Figure 3.
be addressed. The direct extraction of the information from the EHR system would require the client to retrieve all relevant documents of the patient at runtime. Depending on the amount and size of the documents, this would take a significant amount of time and therefore result in negative impact on the usability of the solution. This drawback is avoided by designing a service containing pre-extracted and processed observation information.

The approach integrates seamlessly into standards-based EHR systems using the IHE XDS infrastructure. Using the directed submission functionality of the IHE XDR profile, documents can be directly sent to the service extracting the medical data from the document. This OES Service is within the scope of a local installation, e.g. of a hospital network infrastructure. The approach is also expected to scale well under high load since the extraction process itself is not carried out on a central infrastructure. The data itself are stored in a centralized service, the Observation Broker. This service is able to generate the patient summary itself. The output will either be an On-demand document [22] or a HL7 FHIR based query interface. The implemented prototype proves that it could seamlessly fit into a standard based IHE compliant product and does not require major additions to already existing workflows and standards as they are recommended in large eHealth projects like ELGA [24].

Despite these advantages, there has to be some additional work executed concerning the context and access rights. EHR systems, especially in the IHE XDS environment, are commonly built on an access control system focusing on restricting user access according to rules referencing the XDS document metadata, the role of the user, and the presence of a relationship or association between the user and the patient. As the referenced approaches within this architecture separate the discrete medical data from the document container, a concept needs to be elaborated, to efficiently establish a connection between the document metadata based access control system and the extracted discrete data segments. Another open topic is the auditing requirement of accessing the patient summary. While audit requirements for access to clinical documents is quite clearly defined by standardization units such as IHE or national laws such as ELGA, the audit specification for access to extracted discrete data elements or generated values are less clear. This concerns the pure information of the access to the information as well as what information is shown, when the data are accessed by a certain user.

Conclusion

Providing a summarized and aggregated view of the patients most essential information is an important feature for users of large scale EHR systems. To achieve this, discrete values to information must be provided in addition to achieving this in document-based EHR systems implementing the IHE XDS standard. This information can be extracted from the structured CDA document. Establishing this extraction process in the workflow of registering documents allows the processing of the documents without triggering automated, consuming side transactions, which are regarded as suspicious by patients and users. Additionally, extracting the information in the registration process has a positive effect on the performance, since the information is already present as discrete values and must not be gathered on the fly while the user is waiting for the information. It is, however, still an open challenge on how to restrict the access to the extracted information. Due to the document based nature of IHE XDS EHR systems the access control system of such deployments also work on a document

Discussion

The objective of this paper was to elaborate on a conceptual architecture on a technical level of how patient summaries can be generated on the fly in an IHE standard based infrastructure. Starting off with a literature review, the need for an architecture solving this problem could be confirmed. The literature review—although the queries were conducted using broad search terms—resulted in only three relevant approaches. An explanation for this circumstance might be that standard based XDS EHR systems just started to be widely established in the last years. In contrast to the other approaches, the workflow suggested in this paper tries to integrate into the registering process of medical documents. Capturing the data in the phase of registering allows the extraction of concrete data from the documents without executing automated transactions that do not involve human actors. Automated non-user-based, transactions are always regarded as suspicious and hard to explain to the patient who will see the automated access in the audit logs of the EHR, a functionality of EHR systems that is crucial for patient acceptance and in many countries required by law. [5]. In addition, using this approach, quality requirements addressing performance and feasibility can also

Another aspect that needs to be considered is the management of data that is needed from the extraction process. Using this workflow, the OES receives the whole document metadata in the initiating ITI-41. Using this information, the service is capable of deciding which documents are relevant for the extraction process and which are not. Additionally, in the document analysis process, the service can decide which information is sent to the OBS and which is not. This, however, is likely to be defined by the scenario the services operate in. This avoids the unnecessary duplication of irrelevant data.
level. Solving this problem needs additional research and will be the focus of future work.

Analysis of HL7 EHRS Functional Model and Suggested Applications in China

Haibin Meng, Huajian Mao, Chenyang Chi, Dongsheng Zhao

Institute of Health Service and Medical Information, Academy of Military Medical Sciences, Beijing, China

Abstract

HL7 electronic health record system (EHRS) functional model is an international standard which gives scientific instructions for EHRS design and implementation. It has the features of technological irrelevancy, requirement hierarchy and functional comprehensiveness. It is composed of overarching, care provision, care provision support, administrative support, population health support, record infrastructure and trusted infrastructure. This paper describes the functionalities of each section in detail. To apply this functional model, the history of Chinese health information system construction is reviewed and the weakness is analyzed as a basis. Then this paper gives suggestions on the construction of health information system in China: to enhance the functionality of healthcare systems, to enhance the information network function of regional health information network (RHIN), and to redesign the trust architecture of RHIN.

Keywords:
Electronic Health Records; Models, Theoretical; Suggestion

Introduction

An Electronic Health Record (EHR) is a repository of information regarding the health status of a subject of care in computer processable form. Electronic Health Record System (EHRS) is a set of components that form the mechanism by which electronic health records are created, used, stored and retrieved, including people, data, rules and procedures, processing and storage devices, and communication and support facilities [1]. EHRS functional model (EHRS FM) defines a standard functionality list that presents in an EHRS [2]. As a core model, it determines the main functionality framework that an EHRS should have. At present, China is on the process of constructing interoperable population health information networks [3]. It is essential to get theoretical instructions from the EHRS FM. In this paper, we introduce the history and principles of HL7 (Health Level 7) EHRS FM, and describes the main content of HL7 EHRS FM Release 2 (R2) in detail. Then we review the history of Chinese health information system construction and analyze the weakness of this construction mode. Further, we give suggestions on applying EHRS FM to improve the health information system construction in China.

HL7 EHRS FM

History of HL7 EHRS FM

The research of HL7 EHRS FM can be traced back to April, 2003. It was sponsored by HL7 workgroup. In July 2004, it was approved as a draft standard for trial use. The HL7 EHRS FM R1 was released in February 2007 and became the ANSI standard. The HL7 EHRS FM R1.1 was released in November 2009 and was accepted as an international standard ISO/HL7 10781 [4]. In April 2014, the HL7 EHRS FM R2 was released. Compared with the previous edition, this edition made fundamental change by proposing an entirely new architecture of EHRS FM. It became the ISO standard in 2015 [5].

Principles of HL7 EHRS FM

The principles of HL7 EHRS FM can be summarized as technologically irrelevancy, requirement hierarchy, and functional comprehensiveness.

Technologically Irrelevancy

With the development of information technology, new technologies emerge continuously. The functionalities of EHRS are constantly implemented by new technology, but the functionality framework of EHRS is relatively stable. Therefore, one principle of EHRS FM is to separate the functional framework from its implementation. The technologically irrelevancy is realized by defining the scope and content of EHRS functionalities instead of the technological details of EHRS.

Requirement Hierarchy

Owing to the diversification of EHRS, the actual EHRS conforms to a specific functional profile which is a subset of the EHRS functional model. The conformance criteria have two levels: the required criteria and optional criteria. The required criteria are expressed by mandatory word shall. The optional criteria can be devided into two sub-levels. Suggested criteria are expressed by word should. Permit criteria are expressed by word may. Requirement hierarchy bring about the flexibility of EHRS FM. It can meet the needs of various application situations and adapt to various development stages of EHRS.

Functional Comprehensiveness

Unlike the functional model of common information systems, HL7 EHRS FM greatly extends the scope of EHRS functionalities. Especially in the arena of information network architecture and trust architecture. It embodies the functional comprehensiveness of EHRS.

Description of HL7 EHRS FM R2

Figure 1 shows the general structure of HL7 EHRS FM R2. It consists of 7 sections, which are Overarching (OV), Care Provision (CP), Care Provision Support (CPS), Administrative Support (AS), Population Health Support (PHS), Record Infrastructure (RI) and Trusted Infrastructure (TI). Each section contains functionality list described by ID, type, name, statement, description and conformance criteria.
**Overarching (OV)**

The Overarching section contains conformance criteria that apply to all EHRs. There are 2 functionalities and 33 conformance criteria in this section, including health record report and output, record lifecycle management, security management, terminology service and system management.

**Care Provision (CP)**

This section contains functionalities and conformance criteria required to provide direct care to a specific patient and practice of healthcare. Organized in general flow of an encounter, these functionalities can be used as EHR supporting functionalities to various healthcare systems. There are 41 functionalities and 494 conformance criteria organized in 9 categories, which are managing clinical history, rendering externally-sourced information, managing clinical documentation, managing orders, managing results, managing medication/immunization/treatment administration, managing future care, managing patient education & communication, and managing care coordination and reporting.

**Care Provision Support (CPS)**

This section contains functionalities that support the provision of care. It has 76 functionalities and 559 conformance criteria. They are classified into 10 categories as record management, supporting externally-sourced clinical documents, supporting clinical documentation, supporting orders, supporting for results, supporting treatment administration, supporting future care, supporting patient education and communication, supporting care coordination and reporting, and managing user help.

**Administration Support (AS)**

The Administration Support section includes functionalities that provide support for the management of the clinical practice and give assistance to the administrative and financial operations, such as resource management, workflow, and communication with patients and healthcare providers. It also provides support for managing non-clinical administrative information on patients and providers. It has 55 functionalities and 249 conformance criteria. They are categorized as provider information management, patient demographics and location management and synchronization, personal health record (PHR) interaction management, communication management, clinical workflow tasking management, resource availability management, encounter/episode of care management, information access for supplemental use, and administrative transaction management.

**Population Health Support (POP)**

This section includes functionalities for supporting public health management and disease prevention and control. It focuses on special group of people, such as chronological disease group, women, and children. These functionalities can support data aggregation for medical research, public health promotion, and improving the quality of care. Besides, this section also includes functionalities about protecting patient privacy and supporting patient consents for the secondary uses of medical records. There are 18 functionalities and 108 conformance criteria in this section. They belong to 10 categories: support for health maintenance/preventative care/wellness, support for population-based epidemiological investigation, support for notification and response, support for monitoring response notifications regarding a specific patient's health, support for donor management, measurement/analysis/research and reports, public health related updates, de-identified data request management, support for consistent healthcare management of patient groups or populations, and managing population health study related identifiers.

**Record Infrastructure (RI)**

This section consists of functionalities about record management. It can be implemented within the architecture of a single system or across tightly-coupled systems. There are 37 functionalities (including subfunctionalities) and 186 conformance criteria organized in 3 categories, including record lifecycle and lifespan, record synchronization and record archive and restore.

**Trust Infrastructure (TI)**

This section consists of functionalities related to EHRs trust infrastructure. These functionalities are fundamental to system operations, security, efficiency, data integration, privacy/confidentiality and interoperability with other systems. There are 93 functionalities and 681 conformance criteria organized in 9 categories, including security, audit, registry and directory services, standard terminology and terminology services, standards-based interoperability, business rules management, workflow management, database backup and recovery, and system and performance management.

**Review of Chinese Health System Development**

The Chinese government regard information technology as an important part of modern medicine. Health system construction is an essential part of health reform in China. The development of Chinese health information system can be divided into three stages, which are shown as below [6].

**Stage 1 - Application of Computer Software**

This stage is featured as the application of single computer software, such as finance management and medicine management. In this period, computer software is used to replace artificial operation. It is independent and the power of information technology is not sufficiently revealed.

**Stage 2 - Construction of business systems**

This stage is featured as the construction of various healthcare systems, such as hospital information system (HIS), community healthcare system, physical examination system, disease prevention and control system, and public health system. These systems realize the automatic process of information and increase work efficiency. Designed separately, they have simple data integration capability, and can only meet the needs of business activities.

**Stage 3 - Construction of Regional Health Information Network**

In this stage, the Chinese government began to develop regional health information network (RHIN) based on EHR [7]. The goal of RHIN construction is to break up the barriers of isolated systems, integrate existing healthcare systems, realize the interoperability and coordination, promote the exchanging and deep mining/analysis of EHR data. Currently, China will build 4 levels of RHINs, which are the national RHIN, provincial RHIN, municipal RHIN and county RHIN [8]. The RHINs are based on EHR and take the responsibilities of the center of health data exchange and application.
Weakness Analysis on Chinese Health System Construction
For a long time, Chinese health system construction has been driven by pure information technology and investment. It can only meet the needs of a specific domain. This construction mode lacks top-level design and theoretical instructions, leading to a large number of isolated systems. To solve these problems, RHINs are built to create an infrastructure where health information can be shared, exchanged and analyzed. But a thorough integration is needed. That is, to apply HL7 EHRS FM to Chinese RHIN construction.

Suggestions on Applying HL7 EHRS FM in China
Broadly speaking, there are three suggestions on applying EHRS FM in China. They are shown as follows.

Enhancing the Functionalities of Chinese Healthcare Systems by Means of the EHRS FM
In the architecture of RHIN, the healthcare systems can only play a role of data provider. Their business functionalities are not enhanced by EHR. This leads to the functional stuffless of these systems. For example, a doctor cannot get the clinical history of patient when making a diagnosis. Therefore, it is needed to extend care provision, care provision support and administration support functionalities to hospital information systems and community healthcare systems. Meanwhile, it is needed to extend population health support functionalities to disease prevention and control/public health system. For example, a doctor cannot get the clinical information generated by medical instrument. As an archive management center, the RHIN has EHR lifecycle management functionalities, such as creating archive, arranging archive, migrating archive, merge/split archive, final archive and archive maintenance. These archive functionalities should be extended as well. Table 1 gives the functionality list that can be applied to Chinese healthcare systems. It is noted that the existing functionalities of healthcare systems are not included.

Table 1 – Functionalities Applied to Chinese Healthcare Systems

</tr>
</tbody>
</table>

Enhancing the Information Network Functionalities of RHIN
In China, the RHINs play a role of EHR data integration and exchange. But the systems to be connected are limited to HIS, disease prevention and control/public health system and community healthcare system. Only limited data types are supported by RHIN, such as structured data, documents and images. Compared with the EHRS FM R2, RHIN should extend the systems to be interfaced, such as physical examination systems or personal health record (PHR) systems. Secondly, the data types should also be extended to be compatible with medical instrument generated data. As an archive management center, the RHIN has EHR lifecycle management functionalities, such as creating archive, arranging archive, migrating archive, merge/split archive, final archive and archive maintenance. These archive functionalities should be extended as well. Table 2 shows the information network functionalities to be enhanced for RHIN in China.

Redesigning the Trust Architecture of RHIN
The traditional concept of information security only contains security and audit. But the new trust infrastructure of HL7 EHRS FM R2 greatly extends this concept. It integrates system management functionalities, such as database backup and recovery and system and performance management. The registry and directory services, standard terminology and terminology services, standards-based interoperability, business rules management, and workflow management are also integrated into the new trust architecture. In China, security design is an important part of RHIN [9]. The security architecture of RHIN includes identity protection, identity authentication, identity management, access control, information encryption, digital signature, anonymization and security audit. Compared with HL7 EHRS FM R2, the security architecture of RHIN is not sufficient in registry and directory services, standard terminology and terminology services, and standards-based interoperability functionalities. Therefore, it needs to be redesigned according to the new trust infrastructure. The new trust architecture is shown in Table 3.
Table 3 – New Trust Infrastructure of RHIN in China

</table>

Conclusions

HL7 EHRS FM R2 is the latest advancement in EHRS functionality design. This version contains several new ideas. China should learn from this advanced international standard to improve the functionality design of health systems and promote the construction and development of RHINs in China.

Are Health Literacy and eHealth Literacy the Same or Different?

Abstract

Many researchers assume that there is a relationship between health literacy and eHealth literacy, yet it is not clear whether the literature supports this assumption. The purpose of this study was to determine if there was a relationship between health and eHealth literacy. To this end, participants’ (n = 36) scores on the Newest Vital Sign (NVS, a health literacy measure) were correlated with the eHealth Literacy Scale (eHEALS, an eHealth literacy measure). This analysis revealed no relationship (r = -.041, p = .81) between the two variables. This finding suggests that eHealth Literacy and health literacy are dissimilar. Several possible explanations of the pattern of results are proposed. Currently, it does not seem prudent to use the eHEALS as the sole measure of eHealth literacy, but rather researchers should continue to complement it with a validated health literacy screening tool.

Keywords:
Health Literacy; Medical Informatics; Consumer Health Information

Introduction

Consumer health information systems and technology are increasingly popular. Citizens are actively seeking health information (e.g., diagnoses, medications, symptoms, treatment options) on the internet as well as using digital tools to help monitor and manage their health. In fact, nearly 6 in 10 (59%) Americans sought health information on the internet at least once during 2012 [1]. Further, consumers are increasingly accessing electronic personal health information (e.g., lab test results, prescriptions, medical history). For example, 2 in 10 Americans accessed their medical record at least once in 2014 [2]. However, this new medium of digital health communication, as well as increased access to personal health information brings challenges observed in traditional paper-based health information and create new challenges unique to using information technology.

It is concerning that an estimated 6 in 10 Canadians have limited health literacy [3]. Similarly, only one in ten Americans were considered to have proficient health literacy with the remainder having intermediate, basic, or below basic health literacy [4]. Health literacy is considered “the degree to which individuals can obtain, process, and understand the basic health information and services they need to make appropriate health decisions” [5]. Thus, people with limited health literacy may not have the necessary skills to acquire and understand health information as well as make optimal health-related decisions. In a review of the literature, limited health literacy was “consistently associated with increased hospitalizations, greater emergency care use, lower use of mammography, lower receipt of influenza vaccine, poorer ability to demonstrate taking medications appropriately, poorer ability to interpret labels and health messages, and, among seniors, poorer overall health status and higher mortality” [6].

Given the potential implications of limited health literacy, the concept of health literacy has gained recognition as an important consideration for designing materials and interventions for health consumers. Several different measures are available for measuring consumers health literacy skills. The scales vary in terms of their evaluation approach, administration time, and national healthcare context appropriateness. However, most health literacy scales generate an objective measure of a consumers’ competency by assessing their skills (e.g., comprehension, numeracy, pronunciation of medical terminology). Currently, there is no consensus on the most appropriate health literacy measure [6].

Given the unique challenges associated with navigating healthcare in the digital era, the concept of eHealth literacy has gained traction and research attention. eHealth literacy is “the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem” [7]. Norman and Skinner [7] proposed the Lily Model to depict eHealth literacy. This model is an amalgamation of six component literacies: computer literacy, information literacy, media literacy, traditional literacy and numeracy, scientific literacy, and health literacy [7].

Unlike health literacy, there is a dearth of tools available for assessing consumers’ levels of eHealth literacy. Recognizing the value of aligning eHealth programs and the skills of their users and building on their Lily Model of eHealth literacy, Norman and Skinner developed the eHEALS [8]. Currently, this is the most commonly used tool for eHealth Literacy assessment [8]. The instrument “was designed for simple, easy administration and thus can be used on its own or incorporated with other measures of health as part of a standard health assessment battery in primary care or to support health promotion planning.” [8]. Since its development, eHEALS has been used for various purposes and translated into other languages [e.g., 9, 10].

Developing measures for any construct can be challenging and health literacy and eHealth literacy are no exceptions. One challenge for measurement development is establishing its validity. Validity is defined as “the extent to which a measure reflects the concept. The measure reflects nothing more or less than that implied by the conceptual definition” [11]. Thus,
whether or not a tool actual measures what it intends to measure can be challenging.

Norman and Skinner identified the potential limitation of it as a self-report rather than empirical observation measure and the implication that it was an index of perceived rather than observed skills [8]. Given this potential shortcoming, the extent of the relationship between eHEALS scores and consumers’ observed eHealth literacy skills has been investigated. One study found no evidence of a relationship between participants’ (n = 88) objective performance eHealth tasks and their eHEALS scores [10]. That is, participants were presented explicit tasks and practical scenarios and then asked to solve a health problem such as “Why is the Swine flu not correct?” [10]. Given the dearth of eHealth literacy instruments and that the the validity of eHEALS has been challenged, many researchers continue to rely on traditional health literacy tools for consumer health informatics research. Further, many researchers infer, either directly or indirectly, that eHealth literacy is grounded in health literacy, which in turn encompasses literacy. However, a discrepancy between literacy and health literacy was reported, whereby fewer people were identified as having low literacy than low health literacy, suggesting health literacy requires additional skills [3]. Thus, it is unwise to assume that health literacy is equivalent to eHealth literacy. Yet, one of the most popular health literacy assessments is based on whether participants are able to pronounce (i.e. a basic literacy skill) medical terms accurately [12] rather than on their comprehension (i.e. a health literacy skill). It is logical for researchers to assume there is a relationship between health literacy and eHealth literacy, given that (a) the primary difference in the definition of these two constructs is how health information is attained (i.e. paper-based vs. electronic resources) and (b) health literacy is a component of the Lily Model [7].

An assumed relationship between health literacy and eHealth literacy is also apparent in methodological approaches. Many researchers administer health literacy measures as a proxy for eHealth literacy rather than using measures developed to assess eHealth literacy itself. Often, this is unlikely to be problematic as these assessments are typically conducted in an applied consumer health information technology context. Thus, using health literacy as a proxy for eHealth literacy may be suboptimal, but other aspects of the study will still reveal whether or not participants have difficulty using electronic health information. Health literacy screening instruments have been reviewed for eHealth applications which is evidence of the popularity of this approach and supports this line of reasoning [13]. Therefore, the purpose of this study was to determine if there was a relationship between health literacy and eHealth literacy. It was hypothesized that there would be at least a moderate, positive correlation (i.e. r > 0.4) between participants’ performance on the NVS (a health literacy measure) and eHEALS (an eHealth literacy measure).

Methods

Participants

This study recruited participants using faculty listserves and posters at the University of Victoria, British Columbia Canada. The participants (n = 36) ranged in age from 18 to 35 years old (M = 23.6 years SD = 3.8) and volunteered to participate. All participants completed both the NVS [14] and eHEALS [8] scales as part of a battery of tests in a larger study.

Apparatus and Materials

The NVS [14] is a 6-question scale used to measure health literacy through comprehension and numeracy skills. Participants must interpret information on a nutrition label to answer the questions correctly [14]. The range of possible scores on the NVS is zero to six and it requires approximately three minutes to administer [14]. Participants’ scores are used to infer the likelihood of whether or not they are likely to have limited health literacy.

The eHEALS [8] is an 8-item self-report scale assessing consumers’ impressions of their ability to seek, appraise, and apply health information gained from electronic resources [8]. The eHEALS asks participants how will they know health resources on the internet in terms of what is available, where and how to find helpful one, how to use them, how to evaluate them, how to differentiate between high and low quality ones, and how to use them to inform their health decision-making. Participants rate each question on a five point likert scale from Strongly Disagree (1 point) to Strongly Agree (5 points) and therefore the range of scores on the eHEALS is 8 to 40. However, Norman and Skinner [8] did not provide explicit instructions for differentiating between eHealth Literacy levels, merely that higher scores (i.e. more Agree an Strongly agree responses) indicate higher levels of eHealth literacy.

The demographic questionnaire and the scales were displayed on a 13 inch MacBook Air. Scales were entered into and administered using survey software.

Procedure

This study was a within-groups design and therefore all participants completed both scales. Participants were told to answer the questions to the best of their ability. If participants had questions, they were encouraged to ask the experimenter who remained nearby in the room. All participants completed the demographic questionnaire first, followed by the NVS [14], and finally the eHEALS [8]. All of the measures were administered online.

Descriptive statistics were computed for participants’ demographics, NVS scores, and eHEALS scores. Additionally, a Pearson product-moment correlation coefficient was computed to assess the relationship between participants’ NVS and eHEALS scores.

Results

Participants

Participants were predominantly female (72.2%, Table 1). As expected, all participants were students, (83.3%) most were enrolled full-time, and half (50%) of the participants reported high school as their highest level of education completed. Five participants (13.9%) spoke a first language other than English.

Newest Vital Sign (NVS) Scores

Participants scored an average of 5.1 (Range 2 to 6, SD = 1.2) on the NVS [14]. The NVS had poor internal consistency (α = 0.57). However, this is likely the result of the limited number of items in the scale as well as the dichotomous (i.e. correct or incorrect) nature of the questions.

The majority of the participants (n = 30, 83%) scored five or six on the NVS, indicating a very low likelihood of having limited health literacy (see Figure 1) and further suggesting that there was a ceiling effect. Six (17%) of the participants had NVS scores of 3 or fewer, indicating the possibility they had limited health literacy. However, there was no indication any participants had a high likelihood of limited health literacy, as no participants scored 0 or 1.

Figure 1 – Participants’ NVS Scores and the Implied Likelihood of Limited Health Literacy

eHEALS Scores

Participants scored an average of 27.9 (Range 17 to 38, SD = 5.5) on the eHEALS, which demonstrated good internal consistency (α = 0.86).

* supplementary questions, not formally part of the eHEALS

A framework was developed to make inferences about participants’ scores on the eHEALS. The neutral score was deemed to be the value a participant would earn by answering all eight eHEALS questions with a neutral response (i.e. 24). Two categories were created on either side of this neutral value to postulate the confidence participants had in their eHealth skills based on their eHEALS scores (see Table 2). A histogram was constructed to assess the distribution of participants’ eHEALS scores based on the categories generated (see Figure 2).

Interestingly, 7 participants (see striped column in Figure 2) predominantly disagreed with eHEALS statements, which suggests they were doubtful of their eHealth literacy skills. The majority of the sample (21, 58.3%) perceived themselves as moderately capable of performing eHealth tasks (Table 3). Only 8 participants scored between 32 and 40 indicating high confidence in their eHealth capabilities.

Relationship Between NVS and eHEALS Scores

A Pearson product-moment correlation coefficient was computed to assess the relationship between participants’ NVS and eHEALS scores. No significant relationship (r = -0.04, p = 0.81) was observed between the two variables (see Figure 3). This suggests that the relationship between eHEALS and NVS is limited or non-existent.

Interestingly, six out of seven participants identified as having low confidence in their eHealth literacy skills scored high (5 or 6) on the NVS. This pattern suggests that despite having strong observed health literacy scores, these participants were doubtful of their ability to accomplish eHealth tasks.

Discussion

Contrary to the hypothesis, no relationship between participants’ scores on the NVS and eHEALS was observed.
Moreover, participants had generally high levels health literacy scores, but their eHealth literacy scores were much more variable. There are several different explanations for this pattern of results.

This finding could be the result of health literacy and eHealth literacy being very distinct concepts. That is, contrary to the hypothesis that health literacy is the foundation of eHealth literacy, the skills required for engaging with electronic health resources are so unique from those required for interacting with paper materials, there is no relationship between an individual’s health literacy and eHealth literacy.

Another possible explanation is that the eHEALS assesses health information seeking and appraisal, whereas the NVS only requires comprehension and application of health information. That is, the NVS provides participants with the health information necessary to answer the questions posed, rather than having to find it and determine its trustworthiness. However, the eHEALS asks participants about all three aspects with respect to health resources on the internet.

These results may have been observed because the eHEALS is a self-report measure, which is a suboptimal measure of actual skills. This argument is supported by evidence that participants’ scores on the eHEALS were not positively related to their performance on actual eHealth tasks [10]. In most circumstances, the weaknesses of self-report measures are that there is a tendency for respondents rate themselves in a more socially desirable (or favourable) manner than what is true in reality. However, the pattern of results from this study suggest that participants are actually more critical of their eHealth literacy skills than one would expect them to perform. That is, despite being able to apply health information successfully (i.e. high NVS scores), participants may be overly doubtful of their eHealth skills. Participants in this study were all university students and as such they may approach information on the internet more cautiously.

The final explanation is that eHEALS is not a valid measure of eHealth literacy. The validity of this tool was previously challenged by the lack of relationship between eHEALS and performance on eHealth tasks [10]. Logically, eHealth task performance and eHEALS scores would have a strong positive correlation if eHEALS actually measured eHealth literacy. In contrast, because health literacy is merely one of eHealth literacy’s multiple facets, a moderate correlation would be expected. However, neither of these expected patterns of results was observed. The weakness of eHEALS may simply be that it is a self-report measure. That is, people may be substantially more or less confident (suggested by this data) in their ability to find, evaluate, and use health resources on the Internet.

Based on their total eHEALS scores, most participants had moderate confidence in their eHealth skills. Almost equal parts of the remaining participants had either high or low confidence in their eHealth skills.

One limitation is that only the paper-based NVS has been validated. However, it was administered digitally in this study. Additionally, the Chronbach’s alpha was low indicating poor internal consistency of the NVS. Another limitation was the relatively small size.

**Conclusion**

Results from this study indicate that people one would expect to be very confident in their eHealth literacy skills (i.e. young, well educated), many people are only moderately confident and some even doubtful. One of the motivations for assessing eHealth literacy is to assess how suitable an eHealth intervention might be for a health consumer. If eHealth literacy skills are low in this demographic, it is likely much worse in populations who more likely to have limited health literacy (e.g., seniors, immigrants). This finding also prompts us to question whether the concepts of health literacy and eHealth literacy need to be revisited, new measures needs to be developed, or both.

If the eHEALS is not a valid measure of eHealth literacy skills, it should not be used as the sole index for eHealth literacy. However, it could still be valuable to use an assessment of
consumers' confidence with eHealth tasks. As a precautionary measure, it would be wise for researchers to continue to administering health literacy screening tools paired with eHEALS in consumer health informatics research. Typically, administering a health literacy measure and eHEALS is not time prohibitive. However, this approach does not serve as a solution.

Despite development of a new eHealth literacy measure [16], and another in development based on a more robust eHealth literacy framework [17], these measures likely have the same weakness as the eHEALS: consumers’ may underestimate or overestimate their eHealth skills, limiting the validity of self-report measures. Researchers are in need of a valid, objective (rather than self-report), rapid measure of eHealth literacy. Perhaps this could be done in by standardizing tasks similar to those in Van der Vaart’s [10] study. However, this type of measure would have develop with careful consideration to control or standardize the test (i.e. participants experience the same events with every administration). The Internet is dynamic and thus, participants attempting tasks in a live environment would introduce variability (e.g., different search results). However, it is important that the tasks used as indices of eHealth literacy are realistic. A simulated internet environment could be used as experimental control over the experience of each participant. Given that health inquiries on the internet predominantly begin with a search engine [1], this is an important eHealth literacy task. Including a search task and requiring participants to assess the quality of search results would a useful and realistic eHealth task. The skill set required for health consumers to navigate and benefit from an increasingly digital landscape is undoubtedly unique from a consumer health in a networked world, J Med Internet Res, 8(2), (2006), e9.

An Exploratory Analysis of Game Telemetry from a Pediatric mHealth Intervention

Rema Padmana, Disha Guptaa, Bhargav Sri Prakash, Chelladurai Krishnan, K. Panchatcharam

*The H. John Heinz III College, Carnegie Mellon University, Pittsburgh, PA, USA, bFriendsLearn, Chennai, India

Abstract

Pediatric obesity is a growing epidemic, with unhealthy eating habits and poor physical activity being major contributors. While video and mobile games have been shown to have a positive impact on behavior change in children, the mechanisms underlying game play that impact outcomes of interest are poorly understood. This research aims to examine the impact of a novel mobile gaming app on the design of behavioral interventions by learning from the rich and unique game telemetry generated from a randomized controlled trial of the app use by school children. In this exploratory analysis, we extract a partial dataset to build and analyze chronological sequences of game plays to understand key patterns in the game mechanics that players utilize as they navigate the game, and possible implications of the results.

Pediatric Obesity; Mobile Apps; Game Telemetry Analysis

Introduction

This research is motivated by the need to explore some of the challenges and related opportunities at the intersection of the rising epidemic of pediatric obesity worldwide [1], healthy eating and physical activity related behavior modification challenges in children [2], and the growing role of gamification and learnification on mobile devices in the lives of these pediatric digital natives [3]. While there is some early evidence of the positive impact of video games on healthy eating behaviors in children [4], the mechanisms underlying these improved outcomes are yet to be understood. To design appropriate interventions in the game environment for children’s behavior formation and change, we need to learn more about the underlying patterns of player behaviors evidenced during gameplay, the goals they are trying to achieve with the game, and their overall gameplay experiences.

In this exploratory study, we analyze game telemetry to understand user interactions from playing Fooya, an iOS/Android based mobile App that has been shown to improve the nutrition-health of children through virtual reality-based immersive mobile gaming which uses Artificial Intelligence to achieve personalized behavior reinforcement [5]. We analyze the interactions with the game choices made by the players in a randomized controlled experiment in a middle school setting. Learning from and associating game playing behaviors with known factors affecting unhealthy eating behaviors and the players’ food choices at the end of the game may provide new insights into the complex interactions between game playing and health behavior changes necessary to design more impactful interventions via games on mobile devices in order to improve pediatric overweight and obesity rates.

Background

Pediatric Obesity

Obesity is an increasingly common epidemic in children. The growing pediatric obesity rate worldwide has serious health consequences such as cancers, diabetes, asthma and shortened life span as well as higher healthcare costs [1; 2; 6]. While there are many factors that contribute to overweight and obesity, diet decisions are a leading cause [1]. Unhealthy eating habits and poor physical activity is a major contributor to the growing obesity epidemic [7]. There is significant ongoing focus on addressing the risk factors and moving the population to a healthier lifestyle through health education/communication and motivation. Establishing healthy eating habits early in life is important because childhood habits are predictive of those in adulthood [7]. There is a clear need to identify effective methods for improving dietary intake and physical activity habits earlier in life that are acceptable to children.

Games on Mobile Devices

Games have been shown to have positive impact on children [8]. Many children spend several hours a day playing video games [3; 4], mostly on mobile devices, a platform through which they can learn about health in a fun and enjoyable way. This may be one approach to address the multi-faceted challenge of the pediatric overweight and obesity epidemic [9, 10].

However, a critical barrier to progress in the field is the lack of understanding about the mechanisms underlying games that impact outcomes of interest. Video games include many levels of challenges, imaginative virtual worlds, and the opportunity to navigate them in distinct ways, alone or in teams [11]. The appeal of discovery may be a strong motivator of these games to some players while others may enjoy the competitive or collaborative nature of the game. Gamification is the studied, thoughtful, and creative application of game design elements to engage the player [11; 12]. Games with a highly directed experience and tiered set of tasks can challenge and motivate players. While much is known about game design, recent research has highlighted the gap in understanding the specific mechanisms that link the game playing behaviors with observed outcomes so that game design as well as re-design can be informed through evidence based knowledge and practices [12-14].

Game Telemetry

Large volumes of data are routinely collected during game play and analyzed in simple ways. Game developers nowadays remotely and unobtrusively monitor every aspect of a game, allowing them to accumulate large amounts of data of the player-game interaction over extended time periods [15]. One type of data collected is the actual clicks made by the player as
they navigate the game, called game telemetry. At the current
time, this clickstream data is used to analyze questions such as
whether players are entering the game or not, if they are
dropping out early or late, if they are playing the game for a
while and then dropping out at some distinct step, and so on.
This type of feedback is made available in real time so that
game developers can track usage and player engagement that
have implications for success of the game.

Learning from clickstream/telemetry data.

This data is a valuable source for developers and game
designers to guide decision-making throughout the game design
process, to understand player movements, reduce production
costs, or uncover bugs, among others. At the same time, the
increasing popularity of online gaming has led to in-game
statistics to improve player experiences by providing
performance summaries and comparisons to others playing the
game. There is now a growing field of game analytics, some of
it focused on using telemetry data to discover and communicate
meaningful patterns in data in the context of game development
and game impact [15]. For example, identifying which paths
result in the longest game time and what game features engage
players in these paths require methods to learn paths from the
detailed telemetry data and then examine the features that
define these paths in unique ways. Hence new approaches that
leverage advanced statistical machine learning methods that
can learn from large volumes of multiple streams of high
dimensional data have the potential to facilitate the analysis of
patterns in telemetry data streams.

Impact on design of behavioral interventions.

There is a growing recognition of the need for more refined
strategies for designing behavioral interventions for complex
health conditions that allow incorporation of personalized
evidence-based knowledge and increased use of data and
information technology to improve health outcomes [16].
Researchers have suggested that behavioral science can provide
new insights to make key design decisions by the designers of
serious video game for health-related games. Future research
needs to investigate the most effective ways to achieve the dual
goals of fun-ness and seriousness [14]. The availability of
highly granular game telemetry from mobile video games
promoting healthy behavior changes, enhanced with data about
food habits and choices, provides a unique opportunity to
develop data-driven, statistically rigorous, models and methods
for learning from this data to provide insights for designing
interventions in mobile video games for diverse health
needs to investigate the most effective ways to achieve the dual

develop data-driven, statistically rigorous, models and methods
for learning from this data to provide insights for designing
interventions in mobile video games for diverse health
conditions that can be further evaluated in actual decision
settings [17]. For example, real-time game data can inform
 designers where players are having difficulties in the game and
can potentially modify the design, perhaps in real time, to
improve that experience.

Methods

Mobile gaming App

fooya!™ is a novel mobile gaming, iOS/Android based App
that has been shown to improve the nutrition-health of children
through virtual reality based immersive mobile gaming that
uses Artificial Intelligence to achieve personalized behavior
reinforcement [5]. fooya!™ has been shown to deliver
statistically significant outcomes, with respect to food choices,
during randomized-controlled clinical trials conducted at the
Baylor College of Medicine’s Children’s Nutrition Research
Center [5]. Researchers at Kaiser Permanente Medical Group
were involved in analyzing longitudinal impact on over 1000
children at multiple sites over a weeklong period during the
ExxonMobil Summer Science Camp [18]. These findings are
significant as increasing awareness and self-efficacy are the
first steps to achieving health behavior change [19]. Outcomes
from these and other trials have shown consistently positive
trends, while also exposing opportunities for product feature
development, enhancement and continuous refinement. This
novel approach to behavior design aims to pave the way for
targeting lifestyle disease prevention by enabling lifelong
healthy lifestyle habits. This may be achieved by instilling
healthier preferences during early childhood and the formative
years of life.

Through game design that achieves a psychological state of
flow for deep cognitive engagement, fooya!™ aims to increase
awareness and induce greater self-efficacy. Underlying health
models enable story telling surrounding topics of metabolic
equilibrium and health balance pertaining to the user’s Avatar.
fooya!™ harnesses multiple core game mechanisms that
deliver a single player and multiplayer experience to achieve
behavior design through a social, mixed reality experience.
Game compulsion loops guide users while getting harder over
time, which makes users think more deeply and strategically,
the more they play. The core engagement mechanism in
fooya!™ adaptively engineers user experience moments that
deliver a highly contextual message through a method of
experiential discovery, as the result of learnification – a design
thinking method of embedding and harnessing contextual
learning within core entertainment. Based on a hypothesis
derived from pediatric neuropsychology, fooya!™ was
developed to deliver innovative therapeutic entertainment to
make healthy behavior change incredibly fun for the children.

While the experimental studies with fooya!™ have shown
promising results as a result of innovations through a Digital
Vaccine candidate technology based on Neuropsychology to
reduce the risk of lifestyle diseases [20], they fail to explain the
mechanisms underlying these improved outcomes. To design
appropriate interventions for behavior formation and change
via video games, we need to learn more about the underlying
mechanisms that link game playing to healthy/unhealthy eating
behaviors. Attracting and maintaining a child’s attention may
be the biggest contribution of video games to health-related
behavior change, but this has not been demonstrated [13].
Game playing is a complex process. The automation of analysis
and visualization of game telemetry is an opportunity for
Artificial Intelligence based personalization for specific users.

Data

A rich and unique data set was generated via a randomized
controlled trial of the use of fooya!™ by school children. With
ethics board approval and informed consent from participants,
a research study was conducted to assess the awareness levels
among urban Indian children regarding diet and lifestyle
behaviors and evaluate the influence of the fooya!™ digital
vaccine intervention, among school-age children in India.
Specifically, the study objectives were to quantify the
effectiveness of fooya!™ on health awareness around eating
right and physical activity; find out the current diet and physical
activity among urban children in India and the factors that affect
them; and assess the extent of their awareness about eating
right and physical activity. Using a pre-test, post-test research
design, a total sample of 90 students from 3 urban schools
between 10-11 years of age, equally split between control and treatment groups and randomly assigned, participated in the study. A structured questionnaire first collected demographics, food habits, self-efficacy in selecting healthy foods, nutritional knowledge, and use and frequency playing video games using validated measures from the literature. Students in the treatment group played the mobile game for up to 20 minutes, while the control group played a board game. Once the game playing was completed, the participants were offered a choice of snacks to assess behavioral health outcomes, and a post-test questionnaire was administered to collect information similar to the pre-test questionnaire. All telemetry data associated with the actual game play by the children was also gathered and de-identified for the purposes of the study.

In the game, children make several decisions with split second timing, such as food choices, destroying bad/unhealthy food robots using the bad foods that are thrown at the player, and saving themselves. If the children collect good/healthy foods, they are in fit-zone for a while, which shields them from bad food robots. Throughout the game, telemetry data is collected across different game levels about bad foods thrown by robots at the player, good foods collected by the player during the game, how many times children read ‘nutrition facts’ and of what kind of food, for how long they were in fit-zone, and how many times they were hit by bad food robots. The activities in each level also sequentially influence activities in the next level, potentially affecting children’s behavior enough to influence their real food choices eventually. By finding patterns in this game playing data, we can investigate the dominant and rare navigation patterns and their paths to the food choices of children. Eventually, a feedback loop in the game design may be needed to also influence them at the right time to make better and healthier food choices. Figure 1 shows a screen shot of the game with all the mechanics detailed above.

(2) The second source of data is the demographic data on the players, met data on the game plays such as playing time, completion status, and so on, and the food choices of the children at the end of the game.

In this exploratory analysis, we extracted a small subset of the de-identified game play data of 14 children who participated in the study in July-August 2016. We conducted a simple descriptive analysis of game mechanics to better understand the flow and critical features of the game in order to design advanced analysis of the play sequences of the full cohort in a future study. In particular, we compare the game sequences of the 14 players in their first level with that in the final level and summarize these differences, though the small sample size limits generalizability of the results.

Analysis

Construction of Event Sequences

Each player’s telemetry data, described earlier, was processed and encoded according to a feature labeling scheme by which every possible feature currently utilized in the game by the players was assigned a distinct feature label. These labeled events are ordered chronologically based on their recorded timestamps. These chronologically ordered sequences of events represent the game playing experience of each player. Both game mechanics, which are techniques refined by designers to engage users in gameplay such as intangible rewards and recognition for achievements, and game dynamics, which include techniques designed to affect the pace of gameplay, such as time limits or countdowns, are used in fooya!™.
Figure 2 displays the game play sequences of 3 children, illustrating both game mechanics and game dynamics. Each path represents multiple levels in the game, with each level comprising different types of interactions. The blue boxes represent robots that are destroyed by the player, the green boxes represent the good/healthy foods they grab during the game and the red boxes represent bad/unhealthy foods that attack the player which they need to dodge. Lastly, the yellow boxes represent the nutritional facts read by the child. Across different players and their levels of play, the number, type and sequences of nodes can greatly vary and is reflective of their game engagement.

For example, in sequence 1, the player begins the game by destroying 2 robots, then grabs a healthy food item, is attacked by a bad/unhealthy food item, grabs 2 good food items, is attacked again by a bad food item and ends the level by reading nutrition facts about three different foods, one of healthy type and 2 of unhealthy type. Sequence 2 of the second player includes fewer actions within the same time limit, while sequence 3 of player 3 has the least and with no access to good food items or nutrition facts on good foods.

In this preliminary study, we first conduct a descriptive summary of the game mechanics and dynamics that are demonstrated by the sequences. Together, this analysis will provide some early insights into the patterns that are utilized by the players as they navigate through the game’s mechanics, reflecting game playing processes and its flow.

Results

The 14 players were equally divided in terms of gender, and the ages of the players were very similar since they were all recruited from the same grade at school. A descriptive summary of the game telemetry displayed in Figure 3 shows that some children played only 3 levels of the game, while others went much farther, with 1 child playing 12 levels of the game over the same duration as the others, though on average, males and females played similar number of levels. Figure 3 also summarizes the game mechanics used by the players in the first and final levels of the game. The aim was to examine changes in the access to different mechanics between these levels by all players, and the differences, if any, by gender. We observe that there is a significant increase in the use of different mechanics between the first and final levels, indicating that the players may be learning to play the game better as they navigate the levels. Furthermore, the differences between male players and female players also increase, particularly in the case of bad foods and robots destroyed.

Figures 4, 5, 6 and 7 display the changes in each of the game features of fooya!™ between the initial and final levels played. Interestingly, fewer Nutritional Facts are looked up by the players, as shown in Figure 4. This may likely be due to the increasing familiarity that the players feel regarding the nutritional content of the foods they encounter which decreases their interest and motivation in looking up this information over and over again, but this needs to be verified across other levels of the game and the post-intervention survey responses. This can be useful as early feedback for game re-design that may require new features to capture and retain the interest of the players in a critical component of the game’s mechanics, which is about teaching nutritional facts associated with good and bad foods in a fun way.

Files 4, 5, 6 and 7 display the changes in each of the game features of fooya!™ between the initial and final levels played. Interestingly, fewer Nutritional Facts are looked up by the players, as shown in Figure 4. This may likely be due to the increasing familiarity that the players feel regarding the nutritional content of the foods they encounter which decreases their interest and motivation in looking up this information over and over again, but this needs to be verified across other levels of the game and the post-intervention survey responses. This can be useful as early feedback for game re-design that may require new features to capture and retain the interest of the players in a critical component of the game’s mechanics, which is about teaching nutritional facts associated with good and bad foods in a fun way.
Discussion

This exploratory study examines some preliminary game sequences of children playing a novel healthy eating related mobile app to gain a better understanding of the use of game mechanics. However, how this may be correlated with food choices at the end of the game is yet to be investigated. The current analysis provides some early indications of players’ interests in using the different game mechanics built into the game and the need to design additional methods to display nutritional information that continues to engage the players throughout the game. Due to the limited number of participants analyzed in this study, it is not possible to generalize the results at this time.

Conclusion

Analysis of game play is challenging due to the multiplicity of game features, mechanics, dynamics and other characteristics. Future research will investigate the use of additional data from a larger set of participants to explore all aspects of game play and their associations with decisions made by the players regarding their food choices and the likely reasons for them based on survey responses. The potential impact of these decisions on pediatric obesity and health costs is a longer term investigation of interest.

Acceptance of Using an Ecosystem of Mobile Apps for Use in Diabetes Clinic for Self-Management of Gestational Diabetes Mellitus

Sarita Paisa, Dave Parrya, Krassie Petrova, Janet Rowan

Abstract

Mobile applications (apps) for self-management of diseases such as diabetes and for general well-being, including keeping track of food, diet, and exercise, are widely available. However, consumers face a flood of new mobile apps in the app stores and have no guidance from clinicians about choosing the appropriate app. As much as clinicians would like to support a patient-centered approach and promote health and wellness mobile apps, they may be unable to provide advice due to the lack of comprehensive and reliable app reviews. This research reviewed a selection of health and wellness mobile apps suitable for the self-management of gestational diabetes mellitus (GDM). A prototype of an ecosystem that integrated the data generated by the apps was built and its usefulness and ease of use were evaluated. The results show that the ecosystem can provide support for GDM self-management by sharing health and wellness data across the diabetes clinic.

Keywords:
Ecosystem; Diabetes Mellitus; Mobile Applications

Introduction and Background

In recent years the Diabetes Clinic at Auckland Hospital has had an overwhelming number of female patients with gestational diabetes mellitus (GDM) [1]. The traditional method of manually recording blood glucose readings and maintaining a food diary is not efficient when compared to the telehealth technologies available today. For example, women are given glucometers and asked to check their blood glucose readings at least four times a day. The glucometer readings can be downloaded to a computer. Newer glucometers can download the glucometer readings to a smart phone using near field communication (NFC).

The currently available mobile applications (apps) for self-managing blood glucose and diet present another possibility. Although women mostly maintain their food diaries on paper, some women prefer to save them electronically in a spreadsheet and are familiar with mobile apps that monitor exercise and calorie intake. However, the clinicians at the clinic had not trialed the mobile apps that may be suitable for GDM self-management. They were not sure which health and wellness apps may be appropriate and felt they were slow in adopting the new technology. This study describes the development of an extensible “ecosystem” of mobile apps that supports GDM self-management by integrating patient data exported by the apps into the ecosystems’ database. Clinicians can use the ecosystem to recommend a suitable app (or apps) to their patients and review the shared data in a clinical context. More specifically, the research focuses on the app selection process and on the evaluation of the ecosystem’s usefulness and ease of use.

Health and Wellness Mobile Apps

There are around 8000 health and wellness mobile apps for managing exercise, healthy living, weight loss, and chronic diseases, available on the two dominant smart phone platforms iPhone and Android [2]. In addition to blood glucose and weight tracking, the common set of functionalities include insulin and carbohydrate tracking, exercise tracking, maintaining a food diary supported by an internal food database, and the ability to share wellness data electronically [3, 4]. For example, My Meal Mate is a smart phone app that allows users to save favorite food combinations and recently logged food entries and to take photographs of food for memory recall [5]. Other useful functionalities include displaying a graph of calories consumed daily and showing the results of the analyses of important macronutrients. In a pilot randomized controlled trial for weight loss it was observed that My Meal Mate had a greater acceptance and satisfaction rating compared to traditional interventions such as using paper based food diaries or online weight loss programs [6].

Mobile App Selection Criteria

It may be difficult for consumers to identify the most suitable app. They can consider the set of features identified above or refer to a review such as Hickman and Elsworthy’s [7]. These authors identify the advantages and disadvantages of health related mobile apps based on a comparison across a range of criteria including cost, app rating by the public, exercise and food data functionality, the ability to share information on social networks, and compatibility with various mobile phone models. However, such reviews quickly become outdated as new and improved apps are added to the app stores.

The number of downloads and installations of an app gives a measure of its popularity. This indicator may be considered as a useful selection criterion, especially if coupled with checking the app reviews published on the app store web site. However, these reviews are not professional and may lack credibility.

For some consumer categories, interface usability may be a very important aspect of the app’s functionality. For example, apps designed for the elderly should have a minimized set of functionalities [8, 9]. The interface should be self-explanatory and convenient to interact with, such as the large buttons used in the eCAALYX (Enhanced Complete Ambient Assisted Living Experiment) app for older people suffering from chronic diseases [8]. Unfortunately, not all app reviews...
consider usability features [10]. Similarly, reviews rarely consider the possibility of integrating patient managed data with electronic health records. Ultimately, consumers have to rely on their own judgement in order to identify, trial, and adopt a suitable app.

Sharing Health and Wellness Data with Clinicians

Most commercially available health and wellness mobile apps have a provision to share generated data by email. A clinician can review the electronically shared data during a subsequent consultation with their patient. However, the data are not readily preserved and stored for future consultations, especially with other clinicians. In followup consultations, the physician, the nurse, or the dietician will have no access to the regular updates provided by the app. Hence, it is desirable to store patient managed health and wellness data in a central system accessible to all members of the clinical team. For example, the free to download iPhone app Easy Diet Diary allows for sharing data with a dietician provided that the dietician has purchased a license for Foodworks, a nutrient analysis software [11]. Easy Diet Diary uses food databases specific to Australia and New Zealand.

Exporting patient managed data to a proprietary database does not allow patients the flexibility to select the app of their choice. Furthermore, it may be convenient for patients to manage multiple health conditions through one health and wellness mobile app. Unfortunately, clinical trials and reviews of commercially available apps provide limited evidence about integrating health and wellness data with clinical systems.

This research set out to create a prototype of an ecosystem of mobile apps and devices that can be used to support GDM self-management. The system accepts, stores, and integrates shared health and wellness data from the ecosystem’s components and makes them available to clinicians to search and review (Figure 1). The study addresses the following two research questions related to the design and implementation of the ecosystem:

RQ1. What are clinician criteria for including health and wellness apps in the ecosystem?

RQ2. What are the perceived usefulness and the perceived ease of use of the ecosystem?

![Figure 1 - An Ecosystem Integrating Health and Wellness Data](image)

Method

A user-centered design approach towards the development of the ecosystem prototype was chosen as it needed to meet the requirements of its potential users, i.e., the clinicians treating women with GDM at the Diabetes Clinic and their patients. Information about the functional requirements and the data elements needed to build the ecosystem was obtained from physicians, obstetricians, dieticians, and midwives who reviewed and evaluated mobile apps with food diary and exercise logging functionalities. Data were gathered through open-ended interviews [12]. The data were analyzed qualitatively in order to identify clinician criteria.

Participants

Two dieticians, a midwife, an obstetrician, and a physician participated in an initial mobile app evaluation round that aimed to extract design requirements. The ecosystem prototype was evaluated for its perceived usefulness and ease of use by the initial five participants, by five other clinicians from the same clinic, and by five patients (women with GDM). No real patient data were stored in the prototype.

Prototype Development

The ecosystem prototype was developed in stages with feedback sought from clinicians. The first round of interviews (with five clinicians) contributed to formulating the user requirements of the prototype. Clinicians were periodically emailed a stakeholder consultation document that provided details about the prototype as it was developed. This approach was chosen because clinician availability was limited, making focus group meetings difficult to organize and convene.

The stakeholder consultation document contained descriptions of the low fidelity prototype interfaces, the navigation features, and the prototype data elements necessary for GDM self-management. It also included a review of health and wellness apps that could potentially be added to the ecosystem. The clinicians trialed the apps specified in the document and provided feedback in a continuous dialogue conducted through email, text messages, and phone calls. As the research progressed, other mobile apps were suggested by the participants and more were also discovered by the researchers.

Results

The stakeholder document initially included samples of the data exported from five health and wellness mobile apps selected by the researchers: My Meal Mate, Glucose Buddy, On Track, Doctor Diet, and Microsoft HealthVault. Sending the initial stakeholder document to clinicians started the process of iteratively and interactively capturing and refining the clinician criteria. Three selection criteria were used. First, all apps needed to support food diary and exercise functionality. Second, all apps needed to allow data sharing with third parties. Third, based on findings that cost was a significant factor influencing consumer’s choice of a mobile app, [13] only free to download apps were considered.

Table 1 shows a summary of the properties of the first five health and wellness mobile apps reviewed by the research participants. All apps supported food diary functionality while four apps supported exercise tracking. However, the absence of a food database, as in the case of the apps OnTrack and Glucose Buddy, would make data entry rather difficult (and potentially inaccurate) as patients would have to fill in all food details.

Four of the apps provided options for exporting data that could be shared with clinicians. The app My Meal Mate did not have a data sharing option. However, the food and exercise data were stored in the user’s mobile phone in a SQLite database. A reverse engineering process that used the app’s internal food database allowed for extraction of data about food and exercise that could be integrated in the ecosystem and shared.
with clinicians. The data also provided nutrient information about the food consumed. However, the app’s food database and nutrient profiles were specific to branded food items found in UK supermarkets and not relevant to New Zealand app users.

Microsoft HealthVault was available as an app for iPhone, but there was no equivalent suitable for Android phones. By default, the apps’ capability to share data about food details with a clinician or a friend was limited. The settings can be changed to allow greater food data sharing. However, the process is not user friendly; it may be difficult for an ordinary user to perform the manipulation.

A drawback of the Doctor Diet app was that it focused on food and diet only. Users would have to install another app in order to record exercise.

The app Easy Diet Diary was added to the ecosystem in a subsequent stakeholder document. It features an easy to enter food diary interface and supports extracting data for later integration within the ecosystem. However, as already mentioned, a clinician would need to purchase a license for the Foodworks app, in order to enable data sharing.

Clinician Criteria

Clinicians reviewed the apps’ properties and functionalities. Their views and opinions were used to derive a set of criteria that mobile health and wellness apps needed to meet in order to be considered for inclusion in the ecosystem.

First, in order to be relevant to GDM self-management, the app needed to provide data about both physical activity and food intake, and also data about glucose level and treatment.

Clinician 4
Reflections physical activity and food diary together with treatment and dosage and sugar level.

Second, it was established that a mere calculation of the calories consumed by the patient was not sufficient as the intention of the app user, in this case, was not to lose weight but to manage their diet in order to control GDM. The type of food, its description, and portion size were important indications that needed to be captured, especially for diabetics and midwives. Such data would help clinicians support women with GDM to interpret glucose readings and manage insulin dosage.

Clinician 1
Yes, it is including pretty much everything that you want to know about: blood glucose, food diary, exercise. Calories will not tell you what you have eaten. Need to choose apps which are usable. You need app(s) which get the calories, carbohydrate breakdown, protein and fat.

However, an app’s capability to record carbohydrate content or carbohydrate counting was not critical as most women had GDM only during pregnancy. Furthermore, such patients may not have the carbohydrate counting skills commonly acquired by women with ongoing Type 1 diabetes. Therefore, the clinic had to develop a different approach when consulting women with GDM. In general, apps focusing on healthy lifestyle support would be suitable and more appropriate for women with GDM.

Clinician 3
Wellness data is representative. Easy to compare food diary, exercise, insulin dosage in comparison with blood glucose.

Only two apps, Glucose Buddy and On Track, satisfied all requirements. These apps allowed food description with portion size, which was required by dieticians and midwives. Thus, the ecosystem that was built following the initial requirement analysis included obtaining and integrating patient health and wellness data generated by Glucose Buddy and On Track. The blood glucose readings from the glucometer were also integrated into the prototype.

Ecosystem Usefulness and Ease of Use

The data extracted from the apps and available in the prototype’s database were reviewed by participants in order to obtain further insights into the suitability of the apps. It was found that the perceived usefulness of the ecosystem was directly related to the perceived usefulness of the data provided by the mobile apps.

Clinicians reviewing the ecosystem found it useful as it succeeded in bringing together, in a single report, data from blood glucose readings, the food diary, and the exercise tracking.

Most of the women with GDM who participated in the research had experience using mobile apps, for example managing their diet, weight, and exercise (step counter). However, they were not knowledgeable about mobile apps that may be suitable for GDM self-management. After reviewing the mobile apps included in the ecosystem, women with GDM became interested in using them. They were enthusiastic about sharing their wellness data with clinicians as it would help them self-manage the condition, benefiting their own health and that of their babies.

Patient 1
(I would) absolutely use it and comfortable to share the data with clinician if suitable apps are available.

Both clinicians and women with GDM found the prototype easy to use as completing a task did not require going through many screen interfaces. For example, viewing a combined report about a food diary, blood glucose readings, exercise, and insulin dosage required, in most cases, one screen.

Most women preferred to log their food entries electronically rather than maintain a paper based record. However, training may be required for some, such as first time smart phone owners. Similarly, clinicians were confident they would learn to use the system as it resembled other hospital systems and would be used often (each time a patient visited the clinic). The study findings about the dimensions of perceived usefulness and ease of use of the ecosystem are presented in Table 2.

It took almost a year to gather the initial requirements, build the prototype, and review the ecosystem. At the end of the
of new apps. Patient participants identified new apps that could be added to the ecosystem in order to increase its scope, e.g., MyFitnessPal and mySugr. Both apps were free to download and available for the most popular smart phones, iPhone and Android. Data generated by the apps could be shared by email.

mySugr had the option to export data in CSV format and could be easily incorporated in the ecosystem, thus extending its range of available apps. MyFitnessPal had the option to generate a report in pdf format. The “premium” (paid for) version of MyFitnessPal allowed sharing collected data with other partnering vendors such as FitBit and JawBone using a private application program interface (API). Although not useful for users with a non-premium account, MyFitnessPal is very popular. If its owners add the data sharing feature to the free version, adding the app to the ecosystem may be considered.

Another potential extension was the already assessed Easy Diet Diary app. It exports data to a proprietary nutrition database (Foodworks). However, its usefulness is rather limited as it is available for iPhone only.

Reviews about health and wellness mobile apps by members of the health care community provided a useful means for identifying more apps that could potentially be added to the ecosystem. For example, a group of dieticians from various hospitals and clinics review apps suitable for self-management of chronic diseases and general well-being. The reviews are published in a web portal accessible to the general public [14]. The reviews consider apps from different user perspectives (i.e., clinician or patient) and also from a technical perspective. The web site contains a list of mobile apps supporting healthy living and managing food, diet, and exercise. The list includes the already mentioned MyFitnessPal and mySugr, and also a paid app called Glooko.

### Extending the Ecosystem

Data interoperability was achieved by mapping the schema of the data coming from a mobile app to the target database in the ecosystem. The ecosystem design allowed the easy inclusion of new apps. Patient participants identified new apps that could be added to the ecosystem in order to increase its scope, e.g., MyFitnessPal and mySugr. Both apps were free to download and available for the most popular smart phones, iPhone and Android. Data generated by the apps could be shared by email.

mySugr had the option to export data in CSV format and could be easily incorporated in the ecosystem, thus extending its range of available apps. MyFitnessPal had the option to generate a report in pdf format. The “premium” (paid for) version of MyFitnessPal allowed sharing collected data with other partnering vendors such as FitBit and JawBone using a private application program interface (API). Although not useful for users with a non-premium account, MyFitnessPal is very popular. If its owners add the data sharing feature to the free version, adding the app to the ecosystem may be considered.

Another potential extension was the already assessed Easy Diet Diary app. It exports data to a proprietary nutrition database (Foodworks). However, its usefulness is rather limited as it is available for iPhone only.

In order to be able to integrate shared data from Glooko in to a central database, the clinic would also need to purchase a license. However, clinics with limited funding may not be able to invest in adding paid apps to the ecosystem unless the benefits in terms of self-management interventions and health outcomes are shown to be of much higher value compared to free apps with similar functional capabilities.

Overall, the prototype showed that an extensible ecosystem of mobile apps suitable for the self-management of GDM can be successfully set up. To support privacy protection, the ecosystem facilitated patient access to their health and wellness data while clinicians had to be authorized by patients in order to access their data. Such practices are recommended by researchers [15, 16].

### Discussion

The ecosystem described above helped demonstrate the potential of using mobile apps in the self-management of GDM. New and improved apps may evolve. With appropriate clinician approval and evaluation, these may be ready for integration into the ecosystem. Evaluation criteria can be developed using the required app features (Table 1) and the usefulness and ease of use dimensions identified in the research (Table 2).

The selected Android and iPhone apps had the capability of exporting data in various formats, either shared through an email or saved in a cloud database. In the first version of the prototype, clinicians suggested that they should upload patient data to the ecosystem’s database themselves. They did not trust the accuracy of the data created by patients and wanted to review them first. Clinicians preferred receiving data through email. In most cases, data in formats such as CSV and XML would open easily without installing additional software. However, the next step (integrating the data in the prototype’s database manually) appeared to be an additional workload for clinicians, especially for midwives who met women with GDM on a regular basis.

Manually managing each patient’s file is not an efficient method of exchanging health data. There is evidence of better health outcomes when patients are involved in the self-management of their own diseases [17, 18]. Patients should be trusted to upload their own wellness data into the prototype accurately, even if patient generated health data are somewhat dissimilar to data captured by clinicians and stored in conventional health information systems. Sharing patient generated data across the clinic is beneficial as it helps clinicians keep track of their patients’ progress remotely and in a cost efficient manner.

Data entry and exporting data from mobile apps to another system is not yet automated and seamless. However, existing APIs have the potential to share patient generated health and wellness data from participating mobile apps and sensor devices, thus enabling the creation of an app ecosystem. Data interoperability is achieved as APIs “know” the source and target data schema. However, it can be expected that future mobile apps will have an API capability of transparently sharing data with other systems. For example, several major commercially available wearable tracking devices for step counting, sleep, and heart beat monitoring already support sharing data with other apps.

Although data interoperability was achieved by mapping data from mobile apps to the target prototype’s database, semantic interoperability is still an issue. Clinical standards such as
SNOMED CT, HL7 and the recently introduced draft version of FHIR do not have the provision to include patient generated health and wellness data.

Conclusion

An ecosystem of mobile apps for GDM self-management was set up for patients seen in Diabetes Clinic at Auckland Hospital. Clinicians reviewed the requirements of the ecosystem through a continuous dialogue and discussion by email, phone conversations, and interviews. The review process helped formulate app selection criteria and identify the usefulness and ease of use dimensions of the ecosystem. The women with GDM who participated in the research were confident that the use of these new technologies would help them.

Promoting health information exchange and system interoperability is a prime objective of the “meaningful use” data sharing framework [19]. Despite potential changes in this, it is likely that in the future, services allowing secure, accurate, and timely health data exchange between consumer-focused systems will be available through APIs. This study contributes to the body of knowledge in the area of electronic sharing of health and wellness data from consumer wellness systems in order to improve the quality of health care and involve citizens as active participants in the health care process.

Establishing Therapeutic Alliance in Mental Health Care via Cooperative Documentation

Anja Perlich, Julia von Thienen, Christoph Meinel
Hasso Plattner Institute, University of Potsdam, Germany

Abstract

In talk-based mental health interventions, treatment outcomes can be decisively improved by enhancing the relationship between patient and therapist. We developed the interactive documentation system Tele-Board MED (TBM) with the goal of supporting patients and doctors in their cooperative task of patient care. The system offers a whiteboard-inspired graphical user interface which allows them to take notes jointly during the treatment session. Two proxy studies were conducted whereby TBM was introduced in a role play that showcased the dialogue in a therapy session. The patient role was played by a volunteer. The audience of human-centered design as well as eHealth experts rated the therapist-patient relationship in a session with and without TBM. The data collected via questionnaires shows that TBM consistently receives a positive rating from study participants (N=36) in the areas of collaboration, communication, patient-doctor relationship, as well as patient empowerment.

Keywords:
Physician-Patient Relations; Patient Participation; Psychotherapy

Introduction

Mental health disorders account for over 40% of all chronic illnesses and are the biggest cause of years lived with disability in the developed countries [1]. One major reason why treatments fail is a lack of engagement by the patients. Recent studies show that technology has the potential of supporting a productive patient-doctor relationship and of promoting patient engagement [2]. However, the use of information and communication technology in talk-based mental health interventions is fairly limited, to a large degree because research in this domain is restricted by sensitivity and social stigma. Symptoms of mental disorders may include anxiety, depressed mood, and obsessive-compulsive or delusional behaviour. Talk-based interventions for diagnostics and treatments are common approaches.

In the domain of mental health care, the therapist-patient relationship is a primary curative component and can be considered a necessary prerequisite for the effectiveness of all therapeutic interventions [3]. The term ‘therapeutic alliance’ is used to describe the ideal patient-provider relationship. This alliance is defined as “a dynamic interactional process in which the patient and provider collaborate to carry out negotiated mutual goals in a shared partnership” [4].

In this paper we elaborate on the support of patient-doctor relationships in psychotherapeutic treatments through the use of cooperative technology. We introduce the documentation system Tele-Board MED (TBM), which aims at supporting doctor-patient interactions in face-to-face clinical encounters. Traditionally, the therapist takes handwritten notes (figure 1a) in order to serve personal purposes, e.g. to fulfil legal duties and to overview the treatment. Inviting patients to access their record is very unlikely, as its legibility and understandability can hardly be guaranteed [5]. In contrast, TBM allows the patient and the care provider to jointly take notes and freely structure them on a whiteboard-inspired graphical user interface (figure 1b). The documentation panels can be filled with digital sticky notes, uploaded images, and visual elements such as scribbles. This way, progress notes, therapy material, and case stories are collected in a digital, visually enhanced patient file. Blank documentation panels can be used, as well as templates for specific tasks or treatment approaches (see figure 2).
Figure 2a – Example of a documentation panel used in anamnesis sessions containing headlines and patient information visible as sticky notes.

Figure 2b – Example of a documentation panel used for behavior analysis based on the SORKC model [6].

Related Work

Tele-Board MED is based on Tele-Board – a digital whiteboard system to support creative teamwork over distances [7]. It is a web application based on HTML5 technology [8], which runs in a web browser and thus on diverse hardware devices, such as a desktop computer, laptop, tablet computer, or interactive whiteboard.

Technology used in mental health care to date strongly focuses on improving the access to services and mostly represents a replication of existing, analogue methods. There are means of electronic communication, such as email or chat to support doctor and patient collaboration. Furthermore, there are technologies aimed at increasing patient engagement. Classic therapy techniques, such as emotion regulation and exposure, can be enhanced by virtual or augmented reality [9, 10]. In addition to technology interventions introduced by the therapist, there are computerized therapy applications that autonomously deliver care, e.g. internet-based interventions for post-traumatic stress disorders [11]. However, in order to not leave patients alone with their problems, Knowles et al. [12] call for more research about computer-mediated therapy looking at the integration of health professional input with computer-delivered content.

Tele-Board MED, as well as the software applications described in the following, fall in the category of computer-mediated therapy. Coyle and Doherty [2] designed the role-playing computer game ‘Personal Investigator’ to be played in therapy sessions by an adolescent patient together with a therapist, who takes the role of a partner in the exploration of a game world. A digital notebook supports the player’s personal reflection. In contrast, TBM strives for a collaborative documentation by both patient and therapist. The mobile phone and web application ‘My Mobile Story’ incorporates the therapeutic agent of telling and re-telling the patient’s story to trigger self-reflection. This is carried out by capturing case information in visual and multimedia-based ways [13]. In contrast to TBM, it seems that collaboration between therapist and patient via the application takes place asynchronously and remotely.

Research Questions

Our research objective with TBM is to increase patient engagement in treatments and to improve the doctor-patient relationship. In this way, the effectiveness of the overall treatment increases. The described study addresses the following questions:

- Can Tele-Board MED help to strengthen the therapeutic alliance between patient and therapist?
- Can Tele-Board MED help to increase the shared knowledge of patient and therapist?

In the following, we describe the study setup, the collection of quantitative data through questionnaires, and the data analysis in comparing a traditional therapy session scenario with a TBM-supported scenario. We discuss our study design and results in depth – and finally conclude with a summary.

Methods

In order to test the effects of Tele-Board MED on therapeutic alliance and patient empowerment, two proxy studies [14] were conducted.

Study Setup

In both studies, TBM was presented in the form of an impromptu role play that showcased a therapeutic dialogue. The first study was conducted in Germany with 8 participants whose professional background was eHealth. We used a digital whiteboard as hardware device. The second study was conducted in the United States with 28 participants from the field of human-centered design. Here, a laptop and projector were used. The role of the psychotherapist was acted by a mental health care professional. In both studies, a person from the audience spontaneously volunteered to act the patient role and shared a personal problem. A short, true-to-life therapy session was carried out on stage.

In both settings, the role play contained two parts, each of which was followed by data collection (see figure 3). First, the therapist used traditional documentation means: handwriting on paper sheets. After about five minutes, a break was taken. Both the audience and the proxy patient were asked to fill out short questionnaires. Afterwards, during the next five minutes of therapeutic conversation, TBM was used as a means of documentation. Then again, audience and “patient” filled out questionnaires.

Statistical Measures

Questionnaires for Data Collection
The questionnaire items represent several aspects of relevance
for patient-doctor collaboration (see table 1). The constructs of
 collaboration, integration, empowerment and communication
represent the four subscales of the Kim Alliance Scale [4]. In
each subscale one or two of the corresponding items were
adopted. The items in table 1 are phrased from the patient
perspective. For the audience questionnaire, the syntax of the
sentences was adapted (e.g. item 2 reads “I feel my therapist
listens to me.” for the patient questionnaire and “The therapist
listens to the patient.” for the audience questionnaire). The
items were rated on a five-point scale, ranging from 2 to -2
(‘clearly so’ [2], ‘seems so’ [1], ‘I don’t know’ [0], ‘doesn’t
seem so’ [-1] and ‘clearly not’ [-2]). Feedback from the first
study led to minor modifications in the questionnaire (one item
was omitted, two new items were added). Thus, most items
were rated by all study participants (N=36), however, item 5
was rated by 8 people and items 8 and 9 were rated by 28
people.

Table 1 – Items used to assess patient-therapist cooperation
with and without Tele-Board MED. The constructs marked
with an (*) are the dimensions of the Kim Alliance Scale [4].

</tbody>
</table>

Statistical Measures
For the statistical analysis of the quantitative questionnaire
data, the software package SPSS Version 22 was used. We
calculated the arithmetic means of both scenarios (traditional
vs. TBM), as well as measures to assess the statistical
significance (two-sided p-values) and the effect size (Cohen’s
d). In order to determine the degree of agreement among the
audience raters, we calculated intra-class correlation
coefficients for single measures and Cronbach’s alpha for
average measures. Coefficients of Pearson, Spearman’s rho and
Kendall’s tau-b were used to measure pairwise correlation
among the two proxy patient raters.

Results
The data of both proxy studies was analyzed together. The
following sections describe the comparison of both scenarios
and provide assessments of statistical significance and
reliability.

Evaluation: Traditional vs. Tele-Board MED
Table 2 shows the arithmetic means (in a range from 2 to -2) of
the ratings for the traditional and the TBM scenario pertaining
to the audience and the volunteering “patients”. For the
audience ratings, dependent t-tests for paired samples with two-
tailed tests of significance (p-values) show the level of
statistical significance. These tests were chosen because each
person provided ratings for the traditional and the TBM setting,
and because there was no a priori knowledge about which
scenario would receive better ratings. Furthermore, Cohen’s d
estimates the effect size of the intervention. Here, the traditional
setting is interpreted as the control condition and the TBM
setting is considered the experimental condition, so that
positive d-values indicate a positive effect of TBM. N
specifies the number of valid answers per item. Due to some
missing replies, and three items not being part of both studies,
N varies across the comparisons.

For the answers of the audience members who volunteered to
be patients, no statistical tests are computed since there are only
two respondents.

Table 2 – Average ratings of questionnaire items (#) for a
traditional therapy setting (Trad.) versus a session with Tele-
Board MED (TBM) listed separately for audience members
and volunteering patients. N specifies the number of
comparisons. A two-sided p-value (p) indicates the level of
statistical significance. Cohen’s d (d) indicates the effect size.

</tr>
</tbody>
</table>

Inter-Rater Reliability
For the ratings by the audience members, intra-class correlation
coefficients for single measures and Cronbach’s alpha for
average measures were calculated.

In the first study with audience ratings of eHealth experts in
Germany (N=7), the intra-class correlation coefficient, calculated with a two-way random model and consistency
analysis, amounts to 0.69 for single measures (i.e. regarding single items). On a level of $p<0.001$, this is statistically significant. In terms of average measures (i.e. regarding the total amount of items), Cronbach’s alpha is 0.94, where $I$ would be the maximum possible. When this analysis is carried out in the second study with audience ratings of human-centered design experts in the United States (N=27), the intra-class correlation yields a coefficient of 0.870 for single measures, which is also significant on a level of $p<0.001$. Here, Cronbach’s alpha for average measures is 0.995. Considering the audience raters of study one and two together (N=34) and only those 12 items (2x6) that were handed out in both studies, the intra-class correlation coefficient amounts to 0.873 for single measures, which is again significant on a level of $p<0.001$. In terms of average measures, a Cronbach’s alpha of 0.996 is obtained.

To assess the inter-rater agreement of the proxy patients, common correlation coefficients were calculated. On metrics ranging from 1 (a perfect positive relationship) to 0 (neutral relationship) and down to -1 (a perfect negative relationship), all measures yield values above 0.8, which is statistically highly significant (Spearman’s rho: 0.89 with $p<0.001$, Pearson: 0.86 with $p<0.001$, Kendall’s tau-b: 0.81 with $p=0.002$).

## Discussion

The use of Tele-Board MED seems to have highly significant positive effects on therapist-patient interactions. Figure 4 displays a chart with the expert ratings regarding the comparison of the traditional versus TBM scenario based on the numbers of table 2 relating to the four items and respective constructs #1 (collaboration), #3 (empowerment), #4 (communication), and #6 (relationship).

The two studies on TBM effects had a differing session content (i.e. each proxy patient introduced an individual problem) and different display devices were in use. The studies were conducted on two different continents and the professional background of the expert audiences varied. These differences are likely to add some variance (“noise”) to the data. Still, the ratings show high intra-class correlations both within and across studies. Therefore, the findings seem all the more reliable. A high concordance indicates that the questionnaire answers seem noncontroversial or obvious. Subjective or culture-specific viewpoints bear little influence on the ratings. Consequently, the participants (despite of belonging to different rater populations) show a striking agreement in their responses along all questionnaire items.

There is a strongly significant effect in favor of TBM in eight out of nine items. Statistically, a p-value below 0.05 is generally considered significant and hence it would be sufficient to support the hypothesis that TBM makes a difference. Here, even p-values below 0.001 are observed, which is remarkable given the relatively small sample sizes. This is indicative of a significant effect (see table 2). It is likewise reflected by Cohen’s d, where values of 0.2 to 0.5 are considered a small effect, values of 0.5 to 0.8 indicate a medium effect and values above 0.8 indicate a large effect [15]. The questionnaire data does not only indicate a large positive effect on almost all scales. There are even shifts from a negative average rating without TBM to a positive rating with TBM. The only variable where the audience does not see a clear positive effect of TBM is item #2 (“The therapist listens to the patient.”). However, the members of the audience who volunteered to take on the patient role do indicate that they experience a positive effect of TBM on this item as well (see table 2, part on the right).

Given that therapeutic alliance is seen as one of the most important factors in predicting patient outcome [3], the concordant results of two proxy studies, carried out on two different continents with two different expert audiences, can be considered very promising. Hence, we conclude that TBM has the potential of delivering more than documentation support, namely strengthening the therapeutic alliance between patient and therapist and increasing their shared knowledge. These findings are in line with qualitative insights from real patient consultation with TBM that showed an increased acceptance of diagnoses and patient-therapist bonding [16].

In future work, experimental assessments in on-site clinical studies should add further data to evaluate TMB.

## Conclusion

We introduced the cooperative documentation system Tele-Board MED as a supportive tool for face-to-face encounters in mental health care. In this domain, characterized by sensitivity and stigma, research studies conducted with substitute persons instead of real patients are an increasingly valued methodological approach. In the proxy studies discussed here, we found evidence that therapy documentation can be turned from a necessity taken care of by the doctor into an intervention that affects treatments positively. TBM creates more benefits than providing patients access to their treatment notes. With great concordance, participants observed positive effects of TBM on the creation of shared knowledge and therapeutic alliance between patient and care provider. The latter aspect indicates that TBM strengthens therapeutic communication, integration, collaboration, and patient empowerment.

Integrating Social Networks and Remote Patient Monitoring Systems to Disseminate Notifications

Hugo A. Ribeiro, Eliseu Germano, Sergio T. Carvalho, Eduardo S. Albuquerque
Instituto de Informática, Universidade Federal de Goiás, Goiânia, Goiás, Brazil

Abstract
Healthcare workforce shortage can be compensated by using information and communication technologies. Remote patient monitoring systems allow us to identify and communicate complications and anomalies. Integrating social networking services into remote patient monitoring systems enables users to manage their relationships. User defined relationships may be used to disseminate healthcare related notifications. Hence this integration leads to quicker interventions and may reduce hospital readmission rate. As a proof of concept, a module was integrated to a remote patient monitoring platform. A mobile application to manage relationships and receive notifications was also developed.

Keywords:
Social Networking; Patient Monitoring; Physiology

Introduction
Healthcare systems might not properly accommodate all patients in the near future. There is a shortage of healthcare professionals according to World Health Organization [1]: healthcare workforce will be short by 12.9 million professionals in 2035. Also, the world population is demanding more care given the increased life expectancy and the occurrence of non-communicable diseases [2]. Remote patient monitoring systems may reduce the stress on healthcare systems. The stress relief is achieved via the use of technologies that enable communication between patients and health professionals at any time. Using information and communication technologies might also reduce personalized care delivery costs for patients who need to constantly visit a healthcare facility. There is evidence that 33% of patients, especially elderly individuals, want to have access to remote patient monitoring technologies. Furthermore, 40% of those elderly patients want technologies that notify their caregivers whenever there is an emergency situation [3].

Remote patient monitoring systems may reduce the stress on healthcare systems. The stress relief is achieved via the use of technologies that enable communication between patients and health professionals at any time. Using information and communication technologies might also reduce personalized care delivery costs for patients who need to constantly visit a healthcare facility. There is evidence that 33% of patients, especially elderly individuals, want to have access to remote patient monitoring technologies. Furthermore, 40% of those elderly patients want technologies that notify their caregivers whenever there is an emergency situation [3].

Social network services can be integrated into remote patient monitoring systems [4-12]. This integration enables users to manage their relationships. User-defined relationships are used to disseminate notifications. In emergency situations, notifications lead to quicker interventions and may reduce hospital admission rate.

This paper presents an architecture for notification emission based on integrating social network services to a remote patient monitoring system. As a proof of concept a module was integrated into a remote patient monitoring platform. A mobile application to manage relationships and receive notifications was also developed.

Methods
Our approach to enable notification dissemination in a remote patient monitoring system consists of the integration of social network services. This research evolved over three phases leading to a proof of concept: conceptual phase, design phase, and application development.

Conceptual Phase
Remote patient monitoring systems are specializations of context-aware systems. In this case, context refers to the patients’ health status. A context-aware system architecture, as proposed by [13, 14] is shown in Figure 1.

![Context-aware systems architecture](image)

Context is acquired (Acquisition Layer) using sensors (Sensing Layer); then represented (Preprocessing Layer), persisted and made available (Storage and Management Layer) to the applications residing on the top layer.

Social networks model and manage relationship contextual information [15]. As a context-aware system, a remote patient monitoring system may use the relationship between entities to provide contextual information [16].

Design Phase
Following the pattern present in social network systems, such as Facebook and Twitter, a user receives notifications regarding his/her relationships. A relationship management service can be seen as an event notification service in a publish/subscribe architecture [17]. Creation and destruction of relationships are mapped to subscribe and unsubscribe operations as shown in Table 1.

Subscriptions are content-based [18]. Messages sent to the event notification service have a field specifying the user who subscribed to the service. Information in this field is used to forward notifications.
Table 1 – Relationship manager correspondence with event notification service

  "payload": "message"
}
```

Figure 2 – Message formatted using JSON

Remote patient monitoring systems following this approach are in accordance with the steps proposed by Morrisey [3]; particularly when it comes to notifying designated responders, initiating rapid interventions.

Application Development

Two applications were developed: a relationship manager and a mobile application.

The Relationship Manager is a module integrated into UbiCare, a remote patient monitoring system being developed at Instituto de Informática [19]. This module was built using Flask1, a web development framework for Python. Relationship data are stored in a MySQL database.

The mobile application, UbiCare Social, consumes the services provided by the Relationship Manager, allowing users to manage their relationships and to receive notifications. This application runs on Android operating system. In addition, Google Cloud Messaging (GCM) push service was used to distribute notifications.

Results

Architecture

Our proof of concept aims to deliver notifications to the caregivers. Notifications are sent whenever the collected physiological data presents an anomaly. Patients’ relationships define the notification recipients.

Figure 3 outlines the architecture. Physiological data are collected and transmitted to the UbiCare platform (1, 2 and 3). Users can also interact with the platform using other applications that may be developed (3).

When a user accesses the UbiCare Social application, a device identifier is requested (A) and set (B). This device identifier is maintained in the UbiCare platform (C). To distribute a notification, the UbiCare platform sends a message and a device identifier list to the push service (D). Device identifiers are processed by the push service and the messages are sent to the caregiver and family devices.

Scenario

Consider a scenario with three actors: one patient, one healthcare professional and the patient’s relative. Their relationships are configured as shown in Figure 4.

In a situation in which the patient is an elderly person in post-operative care, remote patient monitoring systems allow the patient to be transferred to home, reducing the number of

inpatients. Healthcare professionals and family members can assist the patient at home, with minimum impact on the patient’s privacy, as they will be notified whenever a physiological anomaly is detected.

**UbiCare Social**

Relationship Manager services are accessed via an Android application, named UbiCare Social. Considering the Healthcare Professional from Figure 4, UbiCare Social behaviour is as shown in Figures 5(a), 5(b), 5(c) and 5(d). Whenever an anomaly is detected, a message with the Patient identifier is sent to the Event Notifier. Carers’ device identifiers are retrieved and the push service (GCM) is triggered. Healthcare Professional and Family Member will receive a notification as the one show in Figure 6.

**Discussion**

There are research efforts to distribute healthcare related notifications using social network systems [4-12]. Facebook, Twitter, and Google Plus were studied in order to check their suitability to solve this problem [6, 8]. Popular social network platforms have big user bases and provide services via APIs. Despite this, users have minimum control over their data and the platform functionalities. Furthermore, users tend to lack confidence in popular social network platforms. Dedicated social networks, such as the one presented in this paper, have the potential to mitigate data ownership, functionalities extension, and trust issues; especially in a research scenario.

**Figure 5 – Mobile application behaviour**

(a) Login screen  (b) Healthcare professional interests  (c) Users interested in the Healthcare Professional  (d) Other users

**Conclusion**

Social network services may enhance remote patient monitoring systems. This integration leads to quicker interventions and may reduce hospital readmission rate. Further research can be undertaken in the following areas: user acceptance testing, security, privacy, conformance with norms and standards, inclusion of social media services such as an audio-visual communication channel.

Trust Model for Protection of Personal Health Data in a Global Environment

Pekka Ruotsalainen*, Bernd Blobel*

*School for Information Science, University of Tampere, Finland
*Medical Faculty University of Regensburg, Germany

Abstract
Successful health care, eHealth, digital health, and personal health systems increasingly take place in cross-jurisdictional, dynamic and risk-encumbered information space. They require rich amount of personal health information (PHI). Trust is and will be the cornerstone and prerequisite for successful health services. In global environments, trust cannot be expected as granted. In this paper, health service in the global environment is perceived as a meta-system, and a trust management model is developed to support it. The predefined trusting belief currently used in health care is not transferable to global environments. In the authors' model, the level of trust is dynamically calculated from measurable attributes. These attributes describe trust features of the service provider and its environment. The calculated trust value or profile can be used in defining the risk service user has to accept when disclosing PHI, and in definition of additional privacy and security safeguards before disclosing PHI and/or using services.

Keywords:
Trust; Health Records, Personal; Privacy

Introduction
Starting from Hippocratic time, trust has been one of the main cornerstones in successful healthcare. Until now, trust and distrust have not been big questions in today’s health care. Instead, it is expected that both health care services and their information systems occur in a controlled environment where ethical codes and laws guarantee fair and trustworthy information processing. It is also expected that patients intrinsically trust the health care service provider, and believe that information systems and networks that communicate, process, and store patients’ personal health information (PHI) are trustworthy. In other words it is argued that predefined organizational trust is sufficient, and security based access controls guarantee privacy [1].

However, health care in general is in transition. Health care services and information systems are increasingly provided cross-organizationally, across boundaries, and cross jurisdictionally. New services models such as digital health, personal health, health eco-systems, and ubiquitous health take place in global information networks. They are built on using modern information and communication technology (ICT), global communication networks, and applications as service. This implies that service providers, customers, patients, the PHI and applications can operate in different contexts and jurisdictions. Furthermore, the PHI is increasingly collected, used, communicated and stored in environments not regulated by health care or privacy laws, global guidelines, codes of conduct; and fair information processing rules are implemented just poorly or even worse, not at all. It is also common that service provider, service user (a person or patient), medical practitioners, secondary users of PHI and health software developers can all have their own notion of how PHI should and can be used and protected. This may basically differ from the expectations of the data subject and his or her local regulations.

From the standpoint of privacy and trust, the modern global and distributed health service environment is challenging. First, in the context of cross-jurisdictional e-health and personal health services, contextual trust and privacy features cannot be predicted or measured in advance. Secondly, the network itself is unsecure, and the data collector or customer has few or no tools to measure the level of trust. Furthermore, he/she has limited or no power to enforce informed privacy and security decisions concerning the trustworthiness of services and control how, by whom and for what purposes PHI is collected and processed [2]. It is widely accepted that trust and privacy are key enablers for global health care and the use of personal health services. Using the self-regulation principle, industry has developed trust, security and privacy rules for eCommerce. Unfortunately, those rules are most of all developed to support industry’s own business needs, expecting that customers blindly trust on the service provider and accept rules as they are (i.e. take-or-leave principle). Yuan and Ruotsalainen et al. have mentioned that increasingly modern health care and ubiquitous health services are dynamic and take place in unsecure and uncertain environment where no predefined trust cannot be expected [2, 3]. This indicates that current rules used by eCommerce cannot be moved to health services as such.

The authors state that health information is highly sensitive requiring special protection. To enable trustworthiness of global health care and the use of personal health services, there is an urgent need for practical and easy-to-use solutions for trust measurement, trust creation and management. Without such prerequisites, it can be dangerous for a service provider to disclose PHI, and for a customer (persons and patients) to use offered services. In global environments, it is also necessary that customers using services and service providers disclosing the PHI can make rational and information based choices concerning additional safeguards needed, in advance.

This paper is based on the following assumptions: Privacy and trust are interrelated concepts in a way that less trust requires more privacy protection. Trust is situational and context-
dependent. Knowing the trust level of a health service provider enables the service user (patient, person or organization) to make rational choices concerning to what extent it has the willingness to use services, and what amount of PHI it is ready to disclose at certain level of trustworthiness. In global environments, trust features expressed in the form of trust value or trust profile enable the service user to define necessary safeguards before starting the use of services.

**Previous research**

Trust is a multifaceted, context-dependent concept, and a term with many meanings. There is no globally agreed definition for it. Widely used trust models are trusting belief, organization/institutional trust, dispositional trust, recommended trust, direct trust, and computational trust [4]. In the context of global health services, trust can be seen as a process of practical reasoning that leads to the decision to interact with somebody [5]. Institution-based trust deals with structures (e.g. legal protections) that make an environment trustworthy. Institutional trust is the belief that needed structural conditions are present [6]. System trust represents the extent to which a customer believes that the proper structures are in place, i.e. that reasonable safeguards are in place to reduce risk. These safeguards may be represented in form of regulations, guarantees, or stabilizing intermediaries [7].

Ruotsalainen et al. have noted that in networked and ubiquitous health service systems dispositional trust, recommended trust, and direct trust are not much stronger than belief, and organizational trust is static [2]. Because the use of global health services is increasingly dynamic, it requires the possibility to make online trust decisions.

Trust models are often based on use of a pure numerical approach. The mechanisms used to calculate trust values range from simple aggregation of values to the use of probability theory, fuzzy logic, or the use of entropy [8]. The number of past experiences, observation interaction, and recording are also widely used [5].

According to Saadi et al., previously discussed “classical” trust approaches that cannot be adapted to networked and ubiquitous environments such as cross-jurisdictional healthcare and personal health systems where the unpredictability and unreliability of service location, contextual features, regulation and rules make mechanisms inappropriate [9]. Viljanen et al. have defined a trust formulation process using trustors contextual attributes and actions, information attributes, social and ethical attributes and third party information (e.g. certificates or recommendations) [10].

Trust models are developed especially for multi-agent systems, Mobile Area Networks (MANET), and open dynamic and ubiquitous environments [5,11,12]. In MANETs, trust is typically evaluated using transaction history of past interactions and transactions and others recommendations. Another approach is the use of trusted third parties and certificates [13]. Hereby, calculated trust values are deployed as estimates of the service provider’s trustworthiness [14].

Ruotsalainen et al. have proposed the following attributes for trust calculation in pervasive health: truster’s environmental factors and contextual features, ICT systems properties, privacy policy, predictability, transparency and openness, and system’s regulatory compliance [2].

**Methods**

In this paper, the collection and use of the PHI in global environment is perceived as a meta-system characterized by its structure, functions, behaviour, and relevant stakeholders. Using system modelling methods, system analysis and system engineering techniques, a conceptual trust management model for the protection of PHI in global environment is developed.

Based on a careful analysis of findings and proposals from research published in journals and conference proceedings, measurable trust attributes are identified. Attributes are aimed for the evaluation of the level of trust of different kind of health providers and secondary users of the PHI in existing in global environment.

**Results**

Because the global health service environment forms a meta-system, trust should be created between its actors. According Saadi, Sabater-Mir and Zheng [2, 8, 9, 14], the authors state that belief and recommendation based trust solutions are too weak. Instead, dynamic system trust that is based on service provider’s real life measurable features is the most promising approach.

**Trust Management Model**

Because the use of PHI takes place in different contexts, contextual trust approach is needed. According to Jøsang et al., contextual trust describes the extent the data subject can expect that necessary services and institutions are in place in order to support trustworthy communication; and trust implies a decision [15]. As discussed earlier, belief as well as dispositional and recommended trust approaches cannot be used in dynamic, distributed environments, and meaningful trust decisions are impossible without reliable information. Therefore, the approach of calculated contextual system trust that is based on measured features of service providers is selected for the model. Thereby, policies can be used to define what is permitted or prohibited, and what security and privacy obligations the service provider must perform in advance.

The proposed model for trust management in global health services is shown in Figure 1. The model is focused on the processing of PHI in different contexts and environments. The model is developed and presented using UML.

In the model, service providers can be either regulated or nonregulated health service providers, or other entities processing PHI (e.g. secondary users). Non-regulated service providers include institutions beyond regulated healthcare establishments such as personal health systems, personal health and ubiquitous-health services. From a data processing perspective, service providers are represented by different instances such as data creator, data controller and data processors [16]. The data controller manages, stores, and discloses personal health information to data processors. Data processors use disclosed health data on behalf of data controllers [16].
The data controller can be a health care provider/providing organization or the data subject (a person or patient). The data processor is any entity deploying received PHI during its service process. The data processor has own business goals such as offering health service or using PHI for research. In global health settings, the data controller often has no predefined trust to the service provider to whom PHI is disclosed to. Instead it has trust concerns.

The data processor deploys an information system with an appropriate ICT architecture (the concept of a system covers both components and processes, i.e. structure and behaviour of that system). One component of the ICT system is the trust decision application. It is typically an Artificial Intelligence solution.

The environment includes national and international regulations, laws and norms guiding the processing of PHI, e.g., security and privacy regulations.

The business environment is a combination of external and internal factors such as organizational rules and constraints in the framework of national and international regulations. The business context of the data processor in the system in question includes expectations of other parties involved such as the data controller/customer, but also process-specific constraints, technologies, etc.

Global requirements include ethical principles and codes of conduct, international Golden Rules (e.g. Fair Information Practice Principles, OECD principles), standards and international certification requirements (e.g. possible future global privacy regulations for health services).

Because trust and privacy are interrelated in such a way that lower trust requires more privacy safeguards, both trust requirements (e.g. audit-log for transparency, policy based access control as properties of the ICT system, standards for reliability) and privacy requirements such as anonymization and denying the post-release of the PHI have to be managed.

Trust creation provided by the data controller requires that the level of trust of the data processor can be defined, formalized and communicated. In the model, the Trust calculator service (e.g. an agent application) collects necessary information for the calculation of trust level or trust profile of the service provider and communicates this information.

The Trust Requirements service uses information received from the Trust calculator, Trust concerns, Global requirements and service providers Trust features to define rules (policies) the service provider offering health service should follow. System requirements such as audit-log, policy based PHI management, notification, and privacy requirements such as anonymization and denying the post-release of the PHI are expressed in the form of computer understandable policies as defined in ISO 22600. In the proposed model, each service provider is first authenticated and then assigned to a trust value or trust profile. Trust and privacy requirements associated to a service provider are processed by its trust decision application.

The presented model is suitable for both static and dynamic online situations in global environment. For example, the Trust calculator can be a Certification Authority (a Trust CA) that generates trust certificates for service providers, and compares them against data controller’s certificate.

**Trust attributes**

In the developed model, trust attributes are needed and used to measure the amount of trust. Researchers have suggested more than 40 different trust attributes [6, 14, 17, 18, 19, 20] (Table 1). Seppanen et al. have defined benevolence, competence, fairness, honesty, moral integrity, motivation, predictability, and reputation as most common trust attributes [21].

The challenge with most of trust attributes shown in Table 1 is that they are difficult to conceptualize and to measure. Therefore, it is also difficult in global environment to generate common understanding for attributes. For overcoming that problem, the concepts should be represented explicitly using ontology representation tools.

</table>

To make attributes acceptable and implementable at global level, the authors propose the following set of attributes for the calculation of trust when health services are used in global environment:

- Ability and willingness
- Integrity
- Openness and transparency
- Properties if service providers manage the ICT system
- Predictability of promises
- Reliability of service provider’s promises
- Service provider’s environmental factors and contextual features
- Service provider’s regulatory compliancy
- Willingness to follow rules (policies) the data processor define

Attributes presented above form a minimum set of attributes that can be measured in real life situations.

Ability can be calculated from direct measurement and/or from the systems’ past history [2]. Integrity addresses that the service provider accepts rules and meets its promises [18]. This can be measured using systems’ history and other’s witnesses. Openness and transparency means that service provider’s security and privacy policies, audit trail, standards and laws used, evaluation and risk assessment documents are openly available, and the security and privacy breaches will be notified to the data controller. Properties of the service providers’ ICT systems can either be identified from evaluation or assessment reports, with the help of system documents and features expressed in contract documents, or from trust certificates. Predictability concerning service provider’s promises can be measured using systems history or continuous monitoring. Service provider’s contextual and environmental features can be resolved by available information concerning service provider’s location and business goals. Regulatory compliance can be measured using conformance assessment and the regulatory compliance documents. Willingness to follow rules (policies) the data controller has defined can be measured either by direct measurements or by monitoring.

In the model, trust value can be expressed using the scale proposed by Liu [22]: Compromised or malicious, unable to determine trust-level, low trust level, medium, fairly high trust level, and extremely high trust level. For more detailed trust creation, the data controller can use rich trust profiles received from the Trust calculator [2]. Based on calculated trust values, the data subject can define service provider specific data processing policies for all organizations and persons participating in the service provision chain, and for all secondary users [2].

**Discussion**

In this paper, the authors proposed a novel trust formulation and management model for health care and health information systems operating in the global information space. The model enables the data controller to disclose PHI, and the customer to use networked health services, by creating and managing contextual trust across geographical, cultural and jurisdictional borders. The authors have also proposed nine measurable trust attributes which the data controller can use in defining additional service provider specific privacy requirements.

The proposed model is flexible. For example, it accepts the use of certificates. Unfortunately, a typical certificate represents only a digital identity of the users, and is static [9]. Therefore, a trust certificate that can be used for the evaluation of trust level requires much richer information such as the trust profile.

In the model presented, the data controller (data subject or organization controlling the use of PHI) can make informed policy decisions by balancing service benefits expected and own privacy needs against trust level of the data processor. A strength of this model is that it enables the calculation of trust level/profile in cases where only incomplete information of data processor’s trust features is available. The latter situation generates low trust value. In this way, the proposed solution is proactive and stresses the data processor to support openness and transparency. Challenges include the development of trust calculation services and the global agreements on trust attributes. This might require political and legal actions at global level. It is also necessary to test the feasibility of proposed attributes, and standardize their presentation and meaning. In the future, it is also necessary to demonstrate that the proposed solution is technically valid, reliable and easy to use. Globally, the biggest challenge is to make the principle of direct measurement based on calculated trust accepted by health industry, healthcare professionals and organizations. International political, legal, regulatory and organizational actions are needed to make this true.

**Conclusion**

The authors have developed a conceptual model for trust management in global, cross-organizational and cross-jurisdictional health service environment. The model enables the data controller (a person or organization) to evaluate the level of trust-worthiness of the data processor before starting to use services or to disclose PHI. Both regulated healthcare and nonregulated health services models are supported. For trust evaluation/calculation, a set of practical and measurable trust attributes is proposed.

In the model, trust level is expressed as trust value or trust vector. The model enables the data controller to define for the service provider minimum privacy and security safeguards required to be qualified trusted.

PubMedReco: A Real-Time Recommender System for PubMed Citations

Hamman W. Samuel, Osmar R. Zaïane

Department of Computing Science, University of Alberta, Edmonton, Alberta, Canada

Abstract

We present a recommender system, PubMedReco, for real-time suggestions of medical articles from PubMed, a database of over 23 million medical citations. PubMedReco can recommend medical article citations while users are conversing in a synchronous communication environment such as a chat room. Normally, users would have to leave their chat interface to open a new web browser window, and formulate an appropriate search query to retrieve relevant results. PubMedReco automatically generates the search query and shows relevant citations within the same integrated user interface. PubMedReco analyzes relevant keywords associated with the conversation and uses them to search for relevant citations using the PubMed E-utilities programming interface. Our contributions include improvements to the user experience for searching PubMed from within health forums and chat rooms, and a machine learning model for identifying relevant keywords. We demonstrate the feasibility of PubMedReco using BMJ's Doc2Doc forum discussions.

Keywords:
PubMed; Medical Informatics Applications; Information Storage and Retrieval

Introduction

PubMed is the de facto tool for searching biomedical and life sciences literature. PubMed is comprised of the MEDLINE (Medical Literature Analysis and Retrieval System Online) bibliographic database, which covers academic journals on medicine, pharmacy, nursing, dentistry, and medical care, among others, with over 23 million trustworthy and peer-reviewed articles[1]. Essentially, PubMed is the web interface to the MEDLINE database. PubMed is typically used from its home page of the National Center for Biotechnology Information (NCBI), which covers academic journals on medicine, pharmacy, nursing, dentistry, and medical care, among others, with over 23 million trustworthy and peer-reviewed articles[1]. Essentially, PubMed is the web interface to the MEDLINE database. PubMed is typically used from its home page of the National Center for Biotechnology Information (NCBI). PubMed uses the process of Automatic Term Mapping, which matches non-MeSH keywords to the MeSH index. A MeSH translation table is used for each query issued by the user to map the natural language keywords to equivalent MeSH keywords. In order to broaden search results, PubMed also leverages mappings of the search query keywords derived from the Unified Medical Language System (UMLS).

UMLS is a collection of biomedical vocabularies and standards, and PubMed can leverage these vocabularies to expand search queries using hypernyms, hyponyms, synonyms, and other semantic relationships[3]. The interactions between PubMed, MeSH, UMLS, and MEDLINE are depicted in Figure 1.

However, using the PubMed web interface for searching is not ideal when users are in a contained environment such as a chat room or a forum discussion thread. Users would have to leave their current web page in order to go to the PubMed website and retrieve the information they need to look up. Furthermore, users need to have a sense of the context of the overall conversation and the key topics being discussed.

Our proposed recommender system integrates PubMed citations into a unified user experience so that medical citations relevant to the on-going conversation are conveniently accessible for the users. From our survey of existing literature, our proposed system is the first of its kind in the medical domain. It should be noted that access to reading an article depends on the individual user's subscription to PubMed; our system displays only the citation, and a clickable hyperlink to the article conveniently within a chat environment interface.

A recommender system is a set of software tools and algorithms that can give useful suggestions to users[4]. The suggestions are given within the context of the user's domain of interest such as what items to buy or shop for, which new people to connect with, or which new movies to watch. Recommender systems are useful from both the perspectives of the content producers (such as sellers, blog writers, videographers, movie makers, and so on) and the content consumers (such as buyers, readers, fans, etc.). Recommendations enable sifting through large amounts of information previously too massive or complicated to practically navigate. Recommendations also enable users to focus on things that interest them personally, thereby increasing the findability of information.

There are various methods for generating recommendations: content-based, collaborative, community-based, demographic, knowledge-based[4]. Content-based recommendations use keywords to suggest new items that are historically similar to
Recommendation systems in chat rooms have been researched in other domains. PALTask is a personalized automated context-aware web resources listing tool that suggests resources of common interests to users in a chat room[5]. These resources include videos, web articles, and social media links relevant to the conversation. PALTask performs contextual analysis, and determines the context of the conversation based on each conversing user's profile, called Personal Contextual Sphere (PCS), and also from the chat conversation contents. The PCS is determined when the user mentions specific keywords related to their personal interests. As an example, context analysis can determine that a user mentioned a music video in the chat. PALTask can then display links to that music video within the chat window interface.

Another real-time chat recommender system has been proposed for e-commerce websites[6]. The recommender system is based on profiling users while they chat. A user may be interacting with another user to chat about buying things, or may be chatting with a seller. The profile contains five parameters: “unusual”, “cute”, “cool”, “simple”, and “luxurious”, with each parameter having a value 1-5, with 5 being the strongest value. The recommender updates this profile by analyzing chat conversations based on inferring positive and negative connotations of words in the chat with the parameters, and using words with associated positive feedback to query the product catalog and recommend items.

Another research work of interest looks at the role of temporal dynamics in product recommendations[7]. The research focuses on evolving user preferences over time, arguing that traditional methods do not take into account the temporal changes of user preferences. For example, if a user bought a particular baby food from an e-commerce website, it is very likely that they would not be interested in seeing recommendations related to their purchase after a while because the dietary needs of a child would be changing as the child grows. To recommend new items, collaborative filtering-style similarity metrics are used based on transactional history. By using these metrics in cluster-based and graph-based modeling, the system retrieves similar items to recommend.

Stream and event processing systems have also been explored regarding real-time recommendations[8,9]. Streams are sequences of events, and stream systems require high throughput processing, making them ideal for the real-time recommendation approach.

Social news is an example of stream systems, where new stories are continuously being added, and user ratings can instantly affect recommendations for related interesting news. The recommendation engine, StreamRec, uses collaborative filtering and works in two phases: model building and recommendation generation. In the model building phase, a similarity score is computed for user-rating pairs. In the recommendation generation phase, items are given a predicted rating based on the similarity scores, and items with a high predicted rating are suggested.

In both PALTask and the e-commerce recommender, incorporation of temporal context has not been considered. For instance, if keywords are extracted from the entire conversation, some keywords may be outdated because they were discussed hours ago. Moreover, even if the latest chat conversation is being used, it might not give the best recommendations. The latest message might diverge significantly from the overall conversation, and could be an outlier. For the StreamRec engine and the products recommender, reliance on a history of ratings could potentially result in the cold start problem, whereby the initial set of ratings have to be determined arbitrarily in the absence of a history of ratings[10]. Another issue with using historical ratings for determining recommendations is sparsity of data, whereby only a few users might choose to give feedback or ratings.

It should also be noted that PubMedReco is a content-based recommender system for temporal conversations, and not a Time-Aware Recommender System (TARS)[11]. The focus of TARS is on temporal relationships between recommendations, while PubMedReco looks at temporal and contextual links between the keywords needed to provide recommendations.

Methods

To demonstrate the feasibility of PubMedReco, we develop a prototype that is populated with conversations taken from a health forum, thereby simulating a chat-like environment where new messages are being added over time. For evaluation, we look at three aspects of accuracy: selection of relevant keywords, agreement about what constitutes keyword relevance, and correlation between recommended citations and selected keywords.

An overview of the prototype is shown in Figure 2, where users are chatting on the topic of coffee enema. For each new message, medical keywords are extracted. A subset of all the keywords extracted are then used to query PubMed and get related citations. In this way, users can view citations related to the overall conversation without needing to go to the PubMed website, or having to determine which specific keywords to use for querying PubMed.

System Design

The PubMedReco system is outlined in Figure 3. As a new message arrives, it is tokenized via regular expressions into individual keywords. Next, common English stopwords are discarded, and the remaining keywords are retained along with relevant information such as the timestamp of the message containing the keyword. In the next step, the incoming keywords from the new message are looked up in an index of all retrieved keywords, which is initially empty. If the incoming keyword exists, only its related information is updated, including the latest message number containing the keyword. Otherwise, the new keyword is added to the index.

![Chat interface at time t](image)

(a) Chat interface at time t.
The keyword features are converted to binary form for input into the artificial neural network’s neurons, as neuron states are more readily represented as 0 or 1.

This conversion includes the keywords themselves, which are converted to word embeddings using the Word2Vec deep neural network model trained with skip-grams on the entire Doc2Doc dataset[16]. The word embeddings enable each unique keyword to be assigned a corresponding binary vector in the space. Also, keywords with common contexts such as synonyms are positioned close each other in the vector space.

### Training Dataset

Initially, the neural net needs to learn how to associate these features to the groupings by using a training dataset with keywords already classified as relevant or irrelevant. The neural net model is trained by manual annotation of a subset of BMJ’s Doc2Doc forum discussions dataset³. The annotation process involves manually inspecting the keywords for each new incoming message, and marking their relevancy based on the current context. The Doc2Doc forums allow doctors to have online discussions with other doctors on various health-related topics. The temporal nature of forum conversations is ideal for testing PubMedReco, as forum discussions progress over time like online chats. Also, the technical nature of doctors’ conversations makes the dataset suitable for querying PubMed. It should be noted that a forum discussion or chat containing n messages yields n training sets because annotations are made for each new incoming message. The trained model can then be used to predict the relevance of new forum discussions or chats that do not have any manual annotations.

### Citations Retrieval

Once the relevant keywords are selected, they are then used to query the PubMed database programatically using Entrez Programming Utilities (E-utilities), a RESTful programming interface[3]. E-utilities accept natural language queries and converts them into Boolean queries by inserting Boolean operators and using the words as operands. Stemming and lemmatization are also performed on keywords by the E-utilities API which can infer synonyms and other relationships to the query words via UMLS.

E-utilities has options for specifying what citation fields to search within, such as title, abstract, full text (where available), author and others. Our proposed system restricts search to the citation title because our recommendations are ultimately presented as full citation titles. Consequently, the user would decide initial interest or disinterest in the recommendation based on the displayed title. The citations returned can also be sorted using various options available in E-utilities, and we sort by relevancy, which takes into account the frequency of matched keywords within the title. Hence, citations containing more of the search keywords would be ranked higher.

### Evaluation Criteria

As mentioned before, three aspects of PubMedReco need to be evaluated for accuracy: neural net, annotations, and recommended citations.

The neural net needs to be appraised for accuracy, in order to determine how it would perform when given datasets that have no annotations. The evaluation is done via the standard precision metric. A sampling out of the total number of training sets generated is selected, and the precision measured. This process is iteratively done in order to see which random sampling provides the best precision value.

The annotations are related to the performance of the neural net. For evaluating the quality of annotations about the relevance of keywords, we use the Kappa score to compare multiple

---

¹ Merriam-Webster’s Medical Dictionary with Audio API available at [http://www.dictionaryapi.com](http://www.dictionaryapi.com)

² U.S. National Library of Medicine (NLM)’s Systematized Nomenclature of Medicine (SNOMED), International edition

³ This dataset is no longer available on the BMJ website, but is still accessible via the Internet Archive’s Wayback Machine project at [http://web.archive.org/web/20160615110024/doc2doc.bmj.com](http://web.archive.org/web/20160615110024/doc2doc.bmj.com)
annotations made on the same dataset. As baseline, we use arbitrary annotations so that there is no planned correlation between a keyword and its relevance.

Finally, for evaluating the quality of the recommended citations, we use Normalized Discounted Cumulative Gain (NDCG)\cite{13} to quantify whether the recommended citations indeed contain the keywords that were used to query PubMed. NDCG measures both the number of matching keywords in a search hit, as well as the usefulness of the hit based on its position in the results. As baseline, we use the “Title” sorting option within E-utilities, so that the top-\(n\) citations are sorted alphabetically. This sorting option will not rank citations based on number of keyword hits, but rather based on the title’s alphabetic ordering.

Results

Firstly, the results of evaluating the neural net are presented. The Doc2Doc dataset contained a total of 1,400 discussions. Out of these discussions, 10 were used as the training dataset with varying numbers of message threads, averaging 9.80 threads per discussion. The total number of training datasets generated from the 10 discussions was 98. The neural net was trained by iteratively and randomly selecting 50 samples out of the 98 training datasets and choosing the model with the highest accuracy. Figure 4 shows the precision for 20 iterations of the sampling. The average precision was 55.87\%, while the highest precision was 60.80\%.

Secondly, we present the evaluation of the manual annotations. We selected 10 discussions with annotations, and re-annotated them without cross-referencing the previous annotations. An average Kappa score of 51.87\% was achieved, showing borderline acceptable agreement with the annotation method. Figure 5 shows the Kappa scores for the 10 annotated discussions (M), their counter-part annotations (N), and baseline arbitrary annotations (Base).

Thirdly, we present statistics on the quality of the citations using NDCG. We arbitrarily selected 5 discussions and computed NDCG for each query to E-utilities, resulting in 32 data points, and an average number of 6.4 messages in the selected discussions. Figure 6 shows the NDCG values with E-utilities optimal sorting (Relevancy), which averaged 0.798, and also the baseline using E-utilities alphabetic ordering of the citation (Title). Similar results were also achieved for other iterations of arbitrarily selecting 5 discussions.

Discussion

The results show that our approach was able to retrieve citations based on forum discussion, while taking into account the relevance of keywords. Other methods for retrieving keywords in chat rooms rely on static heuristics such as a fixed time window\cite{14}. As an example, only the last 5 messages could be used to determine the keywords for retrieving recommendations. Our method moves away from static heuristics and applies machine learning for dynamic retrieval of relevant keywords. Figure 7 shows how our neural net’s keyword selection relates to a dynamic window metric for three randomly selected Doc2Doc forum discussions over 10 incoming messages. The window is set to the number of messages from the lastest to the one containing the oldest keyword selected by the neural net. Moreover, text summarization methods such as TextRank\cite{15}, and ensemble keyword extraction systems such as AlchemyAPI\textsuperscript{4} are not adequate for extracting keywords to summarize a forum or chat room discussion because they do not take into consideration the decay in relevance of the keywords over time.

A limitation of our study is reliance on forum discussions to simulate chats, instead of actual real-time conversations. This

\textsuperscript{4} AlchemyAPI available at \url{http://www.alchemyapi.com}
impacts our trained neural net because feature properties such as firstTime and lastTime will have relatively much smaller values for real-time discussions. Another area of improvement is increasing the training dataset size, which could improve precision. Furthermore, having multiple annotations would strengthen the quality of the neural net, and also provide insights into whether dynamic time windows are based on per-user preferences.

For future work, we aim to gather data from actual real-time chat logs for medical professionals from our health portal Cardea (currently under development), where patients and medics can share experiences, ask questions, and chat in real-time within specialized areas for patient-patient, patient-medic, and medic-medic discussions. Within Cardea, the recommender system can also be used to suggest related content and citations in the discussion forums. Moreover, we intend to add feedback mechanisms to PubMedReco so users can positively or negatively vote on the recommended citations.

Conclusion

This research presented the PubMedReco recommender system which can analyze a forum or chat discussion to extract the relevant medical terms, and then query PubMed to suggest citations that are related to the ongoing discussion. PubMedReco overcomes the limitation imposed on users of online discussion environments whereby users would have to leave their chat interface to search for medical articles in a new web browser window, and formulate an appropriate search query to retrieve relevant results. We demonstrated the feasibility of PubMedReco using BMJ’s Doc2Doc forum datasets. We also evaluated our system to determine the quality of its neural net’s relevance predictions, the training annotations used, and the recommended citations. To the best of our knowledge, the proposed system is the first of its kind in the medical domain. Unlike other real-time chat recommender systems surveyed that use static time window heuristics, the proposed system presents a novel and dynamic machine learning approach for determining keyword relevance within health forums and chat rooms.

Looking for the Best WOW: Understanding the Nurses’ Needs

Bibiana Schachner, Zulma González, Rodrigo Cano, Daniel Luna, Sonia Benitez

Health Informatics Department, Hospital Italiano de Buenos Aires, Argentina

Abstract

The effective use of nurses’ time for providing increasingly safe, efficient, and patient-centered care is a major concern for healthcare managers as well as for nurses themselves. Different solutions have been used aimed at improving those times by providing nurses with mobile and ‘on wheels’ alternatives for bedside care. Nevertheless, the selection of solutions is still a complicated organizational decision. This paper describes the evaluation of ergonomic characteristics of five local mobile carts for the bedside nursing care at Hospital Italiano de Buenos Aires. Cornell University’s checklist was used for data collection according to five domains: handling, work surface and data load, documents and screen reading, storage and dimensions, and energy and cleaning. Considering the scarcity of literature on needs for WOWs assessment, the findings of this paper represent a valuable approach to the requirements of nurses in real work environments and a support for decision-making based on nursing observations.

Keywords:
Computers; Nurses; Informatics

Introduction

The decrease in time that nurses use to perform tasks related to direct patient care and to document evidence of the care they provided continues to be a challenge for administrators and an unmet demand for nurses [1]. The use of computers and workstations on wheels (COWs and WOWs) is a growing trend for bedside care in healthcare settings. It is an acceptable notion that the use of time and coordination of care will be more effective if devices are used to load the data where they are generated (“point of care”) [2]. However, the best solution has not yet been found and although there are recommendations to take into account while making decisions on the subject, there is little research about it [3,4]. Different health professionals can use WOWs but nurses are the main users, and they use them to record patients’ assessments and to transport medications [3, 5]. Studies show that WOWs for bedside care that are available on the market have high costs and do not include mobile technology and other equipment that serve as support. They also have some other related problems, such as long inactivity times due to battery recharge, inadequate dimensions, difficult handling [6], and designs based on the devices’ ergonomics—and not that of the cart or WOW itself—thus generating low adherence to use [7].

It is imperative for the development of a mobile app for nursing data load at the point of care, and for our nurses’ appraisal and needs to make an assessment and collect information regarding the characteristics of different carts and workstations on wheels. This is also useful for the selection that complies with ergonomic recommendations of these devices in nurses’ bedside care environments.

Methods

Setting

The study was conducted at the Hospital Italiano de Buenos Aires (HIBA), an academic hospital founded in 1853, located in Buenos Aires, Argentina. As a JCI-accredited and stage 6+ HIMSS-EMRAM hospital, HIBA belongs to a nonprofit healthcare network including 25 outpatient centers and 150 offices located in the city of Buenos Aires. It has an infrastructure supporting 750 inpatient beds, 41 operating rooms, and a home care network with 800 beds. The organization employs nearly 2800 physicians, 1600 nurses, and 1900 employees in administrative services and management. In the past 20 years, HIBA has developed and implemented an “in house” health information system, including clinical and administrative data. The electronic health record (EHR), named ITÁLICA, is a modular, problem-oriented, and patient-centered system with different settings (outpatient, inpatient, emergency, and home care). It includes clinical documentation system, medication administration using bar coding (intensive care areas), and computerized provider order entry (CPOE). Sections according to the stages of the nursing care process organize the electronic nursing record. Nurses must also diagnose using NANDA-I taxonomy II diagnoses classification and care plan that is based on the nursing interventions classification (NIC).

Study design

This study was cross-sectional, observational and descriptive work, with mixed methodology.

Phase 1:

We used three workstations on wheels (named Dina, Jordan, and Andrea) from July 21 to August 15, 2016. Different local suppliers provided them according to pre-established requirements based on the various necessary characteristics. The suppliers did not provide WOWs with bar code scanners, computer or mobile devices such as a PC tablet (except for Andrea) (Figure 1), because the purpose was to evaluate the carts alone at this stage and to assess devices and barcode readers in a subsequent stage.

A convenience sample was performed. Data collection was made through observations made by the adult and pediatric general care nurses from four different wards, including five nursing shifts (morning, afternoon, night number 1, night number 2, and weekends). They were provided with a copy of
a Cornell checklist, translated into Spanish, which included ergonomic factors for computer carts in health environment. The Cornell checklist is developed by the Cornell University and represents a guide on considerations to evaluate a single cart or a WOW. Taking into account the anthropometric data of adults in the USA, the Cornell checklist is organized into five sections: a) Cart maneuvering; b) Work surfaces and data input; c) Screen reading; d) Storage/accessories/power; and e) Hygiene in addition to free space for comments. The items of each section have a binary response (Yes/No) option about whether the cart satisfies the item or not. If all items are relevant, the total number of "yes" values can be added at the end of each of the five sections and the overall total score can be summarized at the end of the entire checklist. The maximum possible score is 35 and the higher score represents the computer cart with better ergonomic design. A list of activities to be carried out by the nurses with each computer cart was drawn up in the chosen areas before answering the checklist (Table 3). These activities were presented and explained to the nurse teams. Once the days established in the work plan schedule were met, the cart in a particular area was removed along with the filled checklists and a new cart was delivered to that area. Once the cart had completed its rotation in all the four sectors, it was returned to the Health Informatics Department.

The data based on the responses by the nurses for each cart by area and nursing shift were manually entered into an Excel® data sheet. We performed descriptive statistics for each cart with Stata®13. We used non-parametric Kruskal-Wallis test for independent samples to compare differences between the carts. Then we calculated a pairwise comparison of total scores sorted by each cart with the Dunn’s procedure. Furthermore, comments made in the comment space by the nurses in each ward were analyzed independently by the Informatics nurses to gain additional insight about items that were possibly not in the structured checklist.

**Phase 2:**

Once the data were processed and analyzed, the cart with the best score was returned to the supplier for the necessary adjustments and improvements. A new provider handed over a new cart called Mariano. The WOW ‘ANDREA renewed’ and MARIANO were delivered to the same sectors and teams of nurses who had participated in the Phase 1 from October 20 to November 9 for following the same methodology that we used in the first phase. Then we performed descriptive statistics for each cart, and a t-student test to compare means from the two phases.

**Results**

A total of 59 checklists were completed during the three-week rotation of the carts during the first phase. ANDREA was evaluated 20 times, obtaining a minimum score of seven and a maximum of 34, with a mean of 15.85 points (SD 6.9). Meanwhile DINA was also evaluated 20 times, obtaining a minimum score of three and a maximum of 16, with a mean of 6.7 points (SD 3.2). On the other hand, JORDAN was evaluated 19 times obtaining a minimum score of two and a maximum of 16, with a mean of 7.3 points (SD 3.7). Figure 1 shows the carts evaluated in both the phases and Table 1 summarizes the total number of observations for each cart by sector with respective mean, the standard deviation, as well as the minimum and maximum score obtained per sector. ANDREA got the best scores in the carts observed and it was selected for a new evaluation after its reconfiguration by the supplier. The main improvements requested from ANDREA's supplier were in the areas of the handle with a better grip, the tray and the bracket where the optical scanner would hang, and the main pillar where the internal power cables of the device and battery would fit in. The other two (DINA and JORDAN) were discarded. A Kruskal-Wallis test was performed to compare differences between carts. With a type I error of 5%, at least one of the carts had a total score different from the rest (Chi-squared (23.39 (2d.f.), p = 0.0001). Then, after controlling with Dunn's pairwise comparisons, we encountered statistical significant differences between ANDREA and DINA (4.66, p < 0.00001), ANDREA and JORDAN (4.01, p = 0.0001), and non significant difference between DINA and JORDAN (-0.059, p=0.8280)

A total of 52 checklists were completed during the second phase. The scores obtained by ‘ANDREA renewed’ and MARIANO were similar in general but varied by areas. Nevertheless, the t-student test to compare the means of total scores resulted in a statistic of 0.812 (50 d.f.) and a p value of 0.4209, showing that there is no statistically significant difference for the evaluation of the characteristics evaluated by the nurses with Cornell's checklist.

Table 2 summarized the total number of observations.

**Comments analysis**

We mention the themes that emerged in the first phase from nurses’ comments related to the topics in the Cornell's checklist. Nursing staff in each ward identified several negative features of WOWs: lack of stability and difficulty in maneuvering (DINA), noise, unstable cart wheels, large footprint that made ‘it impossible to walk beside it (JORDAN)’.

</table>

The theme related to the need for more comfortable handles and the basket, as well as the noise when moving the carts emerged again in the second phase. The nurses appreciated the improvements from the previous evaluation for ANDREA, but now it was ‘too big to mobilize considering that patient rooms are small’. Another new element was that the power cable was ‘very short’.

Discussion

We performed an ergonomic assessment of five WOWs for bedside nursing care, seeking to find a solution to difficulties experienced by our nurses in collecting data at the point of care, and also for the purpose of improving communication and coordination of care. We aligned our work with suggested changes in healthcare systems to achieve more effective processes that truly support the way care is delivered and transformed [8][9].

Our evaluation examined the ergonomic characteristics available and desired in mobile stations. ANDREA showed a significant advantage over the other carts in the first phase and administered the medications’, as it was very small or had no containment edges.
renewed ANDREA continued in the race for a new evaluation. None of the carts, however, obtained the maximum score, that is, none has all the required characteristics. Some aspects continue to not meet the needs of some nurses at the start of the third phase. This could suggest a low adherence to cart use in future, even more so if we do not include the devices in this stage. Some aspects represent enhancements, such as inability to rotate the axis of the device used to document the patient care, size of the cart perceived by nurses as 'bulky' and difficult to mobilize. Such aspects limit the storage and efficient mobilization [6] in zones in which they will be deployed.

The results of this work cannot be generalized since it was performed in a single hospital center. Furthermore, there was a lack of consistency in some answers—for example, user answered only a single survey in one ward in Phase 2—probably because they were self-administered by the nursing staff.

ANDREA was provided with a tablet and that feature had not been included during the previous training to the nurses. We had instructed them to ignore it, however, some observations may have been influenced by the mere presence of the device. Two Health Informatics research interns, an Informatics nurse, and an Informatics physician agreed upon and decided on the final version of the English-Spanish translation process. The Cornell University's checklist [10] is neither externally validated nor adapted to Spanish; nevertheless, its use provided us a first approximation to the needs of nurses related to mobile workstations. We could include all the HIBA nursing shifts to strengthen our evaluation instead of using only the weekly day shifts. On the other hand, when we discarded the 'worst' carts in terms of score and reconfigured the best positioned cart, we received better response from the nurses who thought that their input was taken into account.

We benefited from creating an elaborate list of activities—that simulated real-world scenarios in daily practice—before the evaluation. We are about to start a bedside care pilot study, indicating the third phase of WOW evaluation, with a new version of MARiano renewed based on the findings and suggestions of the second phase. We also plan to incorporate a tablet PC, a bar-code scanner, and the test of the mobile app for nursing bedside care.

Abstract

On May 2016, our institution implemented a redesign of the personal health record (PHR) with the aim of enhancing its use. The objective of this research was to know and to understand end users’ opinions as regards PHR functionalities and the difficulties they have addressed while using the new PHR version. Research was based on a self-administered survey, patient interviews and focus groups performed with out-patients. Topics examined: ways of access to the PHR log-in web page, frequency of use, type of device, most used functionalities, the different uses patients gave to PHR, perception as regards the redesign. This research allowed us to know the uses patients give to the PHR in this institution and to understand the difficulties they found in what refers to its re-design. This information constitutes the clue to motivate and accompany PHR users in the process of adoption of a patient portal.

Keywords: Personal Health Records; Person-Centered Design, Consumer Health Information.

Introduction

The Personal Health Record (PHR) has been defined as a set of computer-based tools that allow people to access and coordinate their lifelong health information and make appropriate parts of it available to those who need it [1]. They usually consist of provider-tethered applications that allow patients to electronically access health information documented and managed by a healthcare institution. Although patient portals are already being implemented, it is still unclear in which ways these technologies can influence patient care [2]. Within the aims of PHRs are communication, empowerment, portability, education, participation and self-management [1;3].

To ensure the use of PHRs as a patient engaging and empowering tool regarding healthcare, patient adoption of the tool is crucial. Nevertheless, PHRs have not yet reached the levels of use expected. This fact can contribute to the delay of PHRs in reaching their potential [4]. It is reported in the literature that several issues could be obstructing PHR adoption by patients. Barriers to technology or internet access, and patients’ health literacy levels are some examples [5]. Less attention has been paid to the quality of the patient–provider relationship related to portal use; this may be an important barrier to or facilitator of use [6]. Some patients had expressed their concern over whether this new technology might replace conversations between patients and physicians [7;8].

There are several studies reporting less PHR adoption among ethnic minorities and young healthy adult patients [9]. By contrast, a higher adoption is evidenced in disabled, chronically-ill individuals and their caregivers [10;11]. At present, no clear consensus exists as the reasons of this low PHR adoption.

In May 2016, our institution implemented a redesign of the PHR with the aim of enhancing its use through different changes. Even when the hospital PHR was considered by patients as valuable and useful, their functionalities, accessibility and usability were limited. The needs of the different actors along with technological improvements and possibilities started to grow and thus, the project required a redesign process.

We applied user centre design techniques in each module, so as to improve interfaces, as one of the priorities. Other goals were to rearrange the administrative and clinical functionalities separately, and to adapt PHR to all types of devices. The redesign process was mainly focused on the flow rearrangement of each of the tasks in the working space. For this project to take place, a multidisciplinary working team was constituted. Its members were medical informatics and attending physicians, nurses, software developers and usability analysts. They agreed to work with user centre design and agile development methodology scrum approaches. By this mean, hospital patients not only would be a source of information, but also main characters of this redesign, during an iterative and incremental process in favor of continuous improvement.

The implementation was performed in a gradual manner, starting at January 2016. At first, patients could, optionally, log in to the new version and test it. Those who chose to try it also had the option to go back to the previous version. According to the registered data, between January and April 2016, few PHR users had chosen using the new version (only 10%, from 240 000 users). Once the design, development and testing of the new version was complete, on May 2, 2016, the new PHR version was fully implemented. The choice to use the previous version of PHR was not available any more for any patient. This change result in a significant increase in the users’ help-desk and support requests. From the analysis of the support needs, it came out that the difficulties in the use of the tool were mainly due to the interface changes. Taking this issue into account, we considered the necessity of carrying out inquiries with users/patients. In this context, new interviews, a survey and focus groups were performed.

The aim of this research was to know and to understand end user’ opinions as regards PHR functionalities and the difficulties they have addressed while using the new PHR version. Besides, we analyzed the project lessons learned.
Methods

Settings

The Hospital Italiano de Buenos Aires (HIBA) is a non-profit healthcare academic center founded in 1853. The HIBA has a network of two hospitals with 750 beds (200 for intensive care), 41 operating rooms, 800 home care beds, 25 outpatient clinics and 150 associated private practices located in Buenos Aires city and its suburban area. Between 2013 and 2014, over 45,000 inpatients were admitted to its hospitals, and there were 45,000 surgical procedures (50% ambulatory) and 3,000,000 outpatient visits. Since 1998, the HIBA has run an in-house-developed health information system, which includes clinical and administrative data. It has been recently certified by the HIMSS as level 6+ in the Electronic Medical Record Adoption Model, being the first hospital in Argentina and the second in Latin America reaching this stage. The HIBA health information department, is in charge of the design, development, implementation and maintenance of almost all systems, including the EHR and the PHR, as well as the administrative systems [12;13].

Research carried out in 2014, described the mean age of the PHR users as 55,5 years old, being a 60,5 % female. The rate of registered users was almost 50 % while the rate of use was of 29,1 % [14].

Interviews and focus groups

This qualitative research was based on patient interviews and focus groups. Personal interviews were performed with outpatients in waiting-halls. A semi-structured guide was used for the sessions. Questions for the interview were prepared by our multidisciplinary portal implementation team (physicians, psychologists and nurses). Questions included: the different uses patients gave to PHR, frequency of use, perception as regards the redesign, etc. The recruitment for the interviews was performed in the waiting halls, with the collaboration of the different hospital administrative areas, which facilitated selection of those patients that were waiting to be attended. Each session was integrated by a facilitator and an observer.

In order to recruit participants for the focus groups, an announcement in the hospital web page and in the PHR was publicized. Applicants were asked to complete a form confirming attendance.

A semi-structured methodology with discussion triggered motivations was applied [15;16]. Sessions were conformed by a facilitator (researcher and co-researcher) who conducted the conversation such that all participants could express their opinions concerning the proposed objectives. An observer was in charge of registering the encounters. The introduction was standardized by the researcher/co-researcher of the sessions; the aim of the encounters was explained, without naming any adjective. The focus group researcher/facilitator did not interfere with her particular cultural beliefs or preconceptions with respect to the research subject. Both the focus groups and the interviews were recorded and transcribed for further analysis.

Also, an observer obtained written records at that moment in order to register non-verbal information. This study obtained the approval of the Ethical Committee for research projects of our hospital. Once the aim of the study and the confidentiality of the given information were ensured, all participants gave their written informed consent before being included in the study. The study was conducted according to the World Medical Association Declarations of Helsinki dispositions and the clinical guidelines for best practices ICH E6.

Collection and further analysis of obtained data was carried out by two professionals. It was made by the codification and categorization of data based on a process of constant comparison according to Grounded theory [18]. Researchers reviewed the data collected, and repeated ideas, concepts or elements that became apparent were tagged with codes, which have been extracted from the data. Codes were grouped into concepts and then into categories. These categories serve as an orientation for the presentation of results in this article.

Survey

A self administered survey was conducted with a group of patients, who were selected because of the frequency of PHR use and because they had made suggestions through our support system. The survey was made by usability and qualitative testing experts, based on the need to characterize the way patients use the PHR application. Several topics were examined: ways of access to the PHR log-in web page, frequency of use, type of device, and most used functionalities. Furthermore, surveys considered use of the news section, where patients could find health information. Finally, there was a free text space left for comments. The results of the survey are expressed as a percentage.

Results

Interviews and focus groups

From June to August 2016, fifty one interviews were conducted in waiting halls of traumatology, ophthalmology, gynecology and obstetrics, internal medicine and surgery departments. Participants were from 30 to 80 years old, with an average of 65 years old.

Six focus groups with the participation of twenty six patients were also performed. The participants were from 30 to 95 years old, with an average of 68 years old.

From the analysis of the interviews and focus groups, analytical dimensions arose as follows.

The first one was related to the use patients gave to the PHR. We list the following answers in order of frequency: setting up medical appointments and its scheduling reminder functionality, asking for consultations to specialty physicians and for prescription renewals, visualization of medical bills and medication list visualization. Patients also read PHR news, social announcements, and they use the messaging system to communicate with their primary care physicians.

The second dimension was related to the different problems that came up after the redesign. We could differentiate:

- Technical issues
- Problems specifically related with the new design
- Change resistance
- A spectrum of needs that went from their need to be listened, to the preference to know those individuals who resolve their demands and complaints.

Several comments made by patients during the interviews and focus groups were textually quoted.

Technical issues

Participants named difficulties signing in at the PHR, mistakes on the PHR web page, password issues, problems with the web browser, and difficulties to understand the new interface.

- “At first, some red flags with the label: -The user does not have access- appeared. This means you publicited the new PHR without having the system running properly yet.”
Problems related specifically to the new design

One of main reasons of discomfort with the PHR redesign was patients’ belief that several of the most used functionalities were not available any more. In fact, however, patients were merely not able to find them with the new organization.

- “I cannot enter to the PHR using the explorer browser.”
- “I cannot find the consultations anymore.”
- “Since the format had been changed, I couldn’t send messages to my primary physician. It is hard for me to get familiar with this new format.”
- “I could not find the way to purchase medication.”
- “Before the change, I could visualize my x-rays or ultrasounds, but now, not anymore.”
- “I click, and a sign appears. -The bill have been downloaded- Where it appears downloaded? I do not know where it is.”

Concerning the typography size, patients found it too small. In some cases, they had difficulties understanding the icon meanings.

- “Anterior versions were of easier access. The same with the icon sizes. For example the messaging icon is smaller now.”

Another aspect that appeared was the need to enhance the visibility of certain functionalities, by placing them at the main menu with direct access. By this we mean facilitating patient access to them in a simple and agile manner.

Change resistance

taking into account that every change brings along different effects, PHR users were affected. This inquiry enabled us to understand that even if users might have regular access to information and communication technologies, a digital gap exists. It is acting as a barrier for the adoption of this tool, considering the high average age of our hospital population.

- “I do not understand computers.”
- “I want to avoid having to think. I rather prefer the PHR tell me what to do than me having to ask for the information.”
- “Simplify it. Do not try to improve those things that do not need to be improved.”
- “When the PHR was changed, I got angry because I have to adapt myself.”
- “We have to accept that is a chronological issue. I am sure that if I ask my grandson, he could log in properly.”

Other needs

An underlying finding was the need for patients to be listened to and taken into account when thinking about improving the tool, as well as the need to know those people who work behind the PHR and to be in contact with them.

- “Are you the PHR face?”
- “Now that I get to know you, next time I’ll have a problem with the PHR, I won’t get upset thinking on you.”
- “I am facing important personal problems. However, I wanted to participate in some way. I wanted to be listened.”

Survey

A Survey for 1849 patients was conducted. 668 individuals answered it completely. The response rate was of 36,12%. (Table I)

In relation to the PHR access, 61% of the surveyed answer that they did it though the institutional web page, while 33% used the google browser.

As regards the frequency of PHR’s use, 43,71% answered they used it weekly and 42,07% monthly.

The most used functionality (Fig. 1) was test results visualization (93,41%), followed by appointment scheduling (87,43%) and messaging with primary care physicians (80,39%). Among those of median use we found: Consultation requests (61,68%) and medication purchasing (51,05%). The functionalities reported as least used were: The search of health related information (26,35%), the family group functionality (9,28%), and others (11,23%).

The most used device was the desktop computer (69,6%), followed by notebook (40,1%), cell phone (31,44%) and tablet (15,6%).

Related to the resources utilized to obtain health care information, answers were as follow: Google (45,36%), PHR health information section (35,48%), they did not look for information on the internet (26%), institutional web page (22,46%), and others (6%).

Most users admit knowing the PHR news’ section (73,8%) and it meets their interests of their interest (75%).

After the inquiries, changes were performed. Among them we can mention the increase in the icons’ size according to the users’ requests, and the rearrangement of the application home section.

Aside from these changes to the application, different policies were established to favour communication and accompany the change. The support system was reorganized, instructional materials were sent to users and encounter spaces with users were increased.

After such changes, the support requests though the PHR and the help desks decreased. Beginning with 160 requests/day around the implementation period, this number was reduced to 30/day, most of them related to password neglect or problems with new users, from a total of 360,000 users enrolled to PHR.

Discussion

Denial, anger, bargaining, depression and finally acceptance are stages of grief during the change process. Frustration, hopelessness and anxiety are common feelings and they require acknowledgment of the underlying pain. Allowing time to adapt to the new system, improving functionality when possible and providing good training; these are important tools to help deal with the challenges of change [17].

This experience helped us to understand the vital importance of organizing and increasing specific resources during a PHR implementation as described above. These resources include: Communication, education, support and training, all addressed to patients and professionals. These were some of the lessons learned.

As regards support resources, the need to acquire a new help desk system and reorganize the requests in categories with the aim of optimizing resources is very important. The help desk tool that was available at the implementation period did not allow the tracking of the request orders resolved, help desk referral to other areas or direct contact with the user.
The option of using and testing the new version was only chosen by a few users. Taking this fact into account, it might have been worth developing a better diffusion of the change so as to attract more users during its optional use.

The literature reports significant challenges that could represent an obstacle for the adoption and effectiveness of the PHR, such as computer or internet accessibility limitations or the technical language commonly shown by PHRs[5]. This inquiry enabled us to understand that even if users might have regular access to information and communication technologies, a digital gap exists. It acts as a barrier for the adoption of this tool, considering the high average age of our hospital population.

Finally, the need for patients to be listened to is important (because of non-conformity with the attention received, delays in the medical appointments administrative issues, etc.). Users have shown interest in knowing the “PHR face”. This signifies that for patients, connecting a face and a name and personifying the application in some way, remains important in the virtual realm.

Many patients mentioned this aspect as encouraging them in the will to be part of the designers of the application.

The need to count on a platform serving as a communication source for users, allowing notification of new PHR functionalities or even contingency periods, have been evidenced by this research. Following our experience we are at present working with such a platform.

**Conclusion**

This research allowed us to know the uses patients gave to the PHR in this institution and to understand the difficulties they found in its re-design. This information constitutes the clue to motivate and accompany PHR users in the process of adoption of a patient portal, and its use as a tool to collaborate with their empowerment. During a process of implementation as described in this article, it becomes essential to count on different means of diffusion and training methods. Moreover, the supportive resource must be increased.

Mobile Application for Pregnant Women: What Do Mothers Say?

Janine Sommer, Mariana Daus, María Smith, Daniel Luna

Department of Health Informatics, Hospital Italiano de Buenos Aires

Abstract

Today, health information technologies are constantly expanding and changing, allowing more and more people to use different mobile applications to receive information and control their health condition. Based on the need to implement an application for pregnant women in the Personal Health Record (PHR) of Hospital Italiano de Buenos Aires (HIBA), an Australian survey was carried out to measure the use and utility of a pregnancy application (pregnancy app). Our results were broadly in agreement with the reference values. The survey was distributed through social networks (Facebook and Twitter) during September 2016. We obtained 235 responses from Spanish-speaking women, mostly Argentinian. In conclusion, it could be observed that a pregnancy app offers the possibility of a greater follow-up and provides reassurance to the pregnant women who use it.

Mobile Applications; Pregnancy; Health Records, Personal.

Introduction

Pregnancy is a period in life in which women must get used to a new state and begin to deal with new uncertainties and anxieties. The Internet allows pregnant women to access online discussion sites in order to obtain information about conception, pregnancy and maternity and facilitate communication with other women who are going through the same condition [1]. In this period patients have a great need to look for information. Prenatal education and access to information at this stage is highly valued by women, moreover when it is provided in optimal circumstances and from a safe source [2]. The popularity of pregnancy-related applications could indicate a change towards the empowerment of the patient concerning the provision of maternity care. The traditional model of “shared maternity care” in its functioning needs to incorporate electronic devices. The dependence of healthcare professionals can be reduced by the availability of interactive and personalized information delivered through an application [3].

The most important aspect an application for pregnant women must consider is meeting user needs and being reliable. There is concern regarding the poor quality of many of these applications, since they are not always based on scientific knowledge when providing information or services. Healthcare professionals need to control the quality of information provided by pregnancy applications and identify the needs of women during the prenatal period. Taking this into account we decided to implement in HIBA an application targeted to pregnant women within the Personal Health Record (PHR). The PHR of HIBA is a web-based tool where patients can take an active role in their care, have access to their own health information and also perform certain tasks such as communicating with physicians and asking for an appointment.

In order to inquire about what pregnant women are looking for, we took and translated an Australian survey [1] that had been conducted on the use and utility of a mobile application for pregnancy with the aim of carrying it out in our context. Survey results were analyzed and taken into account for the development of an application for pregnant women within our personal health record.

Setting

Hospital Italiano de Buenos Aires is a tertiary level institution with 150 years of history. It is an academic hospital that covers the entire spectrum of health care: outpatient and inpatient care, emergencies, medical and surgical specialties, critical care, as well as home and chronic disease care. Its informatic development has been achieved from its own initiatives, which led to the appearance of multiple platforms, vocabularies and mechanisms of communication. For more than five years, the institution has been designing and building his own Hospital Information System (HIS) with the objective of linking the great diversity and variety of developments that have been developed over time within the hospital; both in the administrative and clinical layers. This resulted in the incorporation of a greater number of users who currently involve administrative staff, doctors and nurses.

During 2007 the hospital developed the Personal Health Record, a web-based tool that consists on a personal medical record that provides services and access to unified data in multiple applications. It allows patients treated in HIBA health network to interact or consult their clinical or administrative information. Self management and control of its evolution are patient’s objectives. The new PHR not only satisfies these needs, but also enables fluid and instantaneous communication with healthcare professionals. To do this, it takes advantage of the possibilities offered by the current technology and the user’s new means of communication.

Materials and Methods

So as to get to know the use and utility of mobile applications for pregnancy and parenting, an Australian survey [1] was employed. The translated survey consisted of 14 questions on mobile applications for pregnancy, the name and type of application was not asked (we excluded questions about parenting as they were not part of our goal). The survey was distributed through social networks (Facebook and Twitter) and at waiting rooms of the HIBA Women’s Center during September 2016. 235 responses were obtained.
The survey had the following domains:
1. Demographic data (age, country, education level, etc.)
2. Use of mobile applications for pregnancy
3. Usefulness of mobile applications for pregnancy

Results

83.4% of women were pregnant at the time of responding the survey. Of the 235 responses, only 152 (64.7%) women had ever used a mobile application for pregnancy and 40.1% used it frequently. Regarding the utility, 92.1% answered that they had found useful functionalities in the application they used. As a striking fact 64.5% did not check the application information sources and almost 72% did not care if the application used their given personal information.

Discussion

Several studies have shown that pregnant women are using the Internet to look for information related to pregnancy, and that online forums are spaces they use for support and guidance. Researchers are exploring how new technologies, including internet forums, websites, email, YouTube, text messaging and smartphones, can be used to promote maternal and newborn health. Research suggest that these technologies are a new and promising mean for health education and communication [5]. Mobile applications allow patients to record the health information collected at each appointment and track their health. As patients interact with this information, they may become more involved in their care. Thus, patients believe that their role as patients is important, that they have the confidence and knowledge to take action, and that they can adopt behaviors to maintain and improve their health; patients can be able to take actions, ask questions to their healthcare provider, and participate in the decision making process about their treatment, being therefore partners with their provider in their health care. Patient engagement is a factor that affects the interpersonal processes of prenatal care. Interpersonal care processes conceptually and operationally cover three dimensions of clinical care: communication, patient focus on decision making, and interpersonal communication style [6]. With this in mind, we focus on this population to meet their information needs. For the development of the mobile application for pregnant women within the Personal Health Record we first investigated other experiences on the use of mobile applications. Once we found the survey conducted in Australia, and realize that it followed our same research goal, we decided to adapt it locally and apply it in our context in order to draw conclusions and using it as a guidance for the development of the application’s functionalities. We do not find similar experiences regarding this issue in South America, this suggests that although it is demonstrated that mobile applications bring information to the pregnant women and empower them, there is currently lack of evidence and research on this topic in our population.
Regarding the conduction of the survey, social networks employment broadly facilitated survey diffusion. The respondents participation was voluntary and demographic characteristics were heterogenous, which gave us varied and rich opinions. In parallel we conducted the survey in person at the waiting area of the Women’s Center of the Hospital Italiano de Buenos Aires. A total of 235 responses were received; 15% of surveys were conducted in person. Results showed a wide range of app use, from those who have never utilized an application to those who use it every day. Other relevant information such as the importance they gave to the source of information they were consulting, or if they were concerned about the sensitive personal information storage and management within the application was also obtained.

Developing an application according to the needs of the end user is extremely important [7]. Pregnancy is a unique life experience that evokes a range of emotions from great joy and anticipation to paralyzing anxiety. This increase on emotions facilitates a greater demand of experience exchange with others as well as instant connectivity, professional consultation and reassurance needs. The panacea to enjoy and relief from these emotions could be the smartphone and its associated applications. These devices could potentially allow women to communicate, follow the progress of their pregnancy, and relieve distress interactively [3]. Informational applications, which are non-interactive and are in the base of reference, constitute the largest category of applications related to pregnancy. These applications cover a range of topics related to maternal and fetal health, from general pregnancy to more specific information, such as the mother's diet for gestational diabetes. In many ways, their quantity and popularity suggest that there is a significant demand for such information [4]. From this perspective, this study was very significant as its identified the patterns of use and the need of applications in pregnant women, as well as clarifying other aspects that should also be taken into account. This resulting considerations were taken as the basis for the development of a specific application adapted to the needs of women in this condition.

The objective is that pregnant woman can find a tool tailor-designed for her that provides with pertinent information, to carry out a collaborative accompaniment of the healthcare team from the moment of conception through pregnancy period and till childbirth; and provide useful tools that allow users to record moments that they consider as important in a "pregnancy journal." This application will be linked to our PHR created as a tool to empower patients and give them the capability to participate in their own health care.

The access to the application within the same PHR gives the patient the reliability that the offered health contents are created and validated by specialized professionals and endorsed by our institution. The application will be called Personal Portal for Pregnant Women. Its will contain three time lines differentiated by color, with different types of content: clinical (appointments with professionals, medication to be taken), contextual information (development of the baby according to gestational age, changes in the mother and studies to be done in each trimester) and information added by the patient (notes, reminders, photos). The pregnant woman can monitor her pregnancy through the platform, in real time. (Figures 1, 2 and 3). This project, not implemented yet, it is in the last phase of development. Once fully implemented, we will measure its impact as a future line of research.
Conclusions

The survey used allowed us to get to know the reasons why women use a mobile application during pregnancy. Although we already had information related to the Australian population, we wanted to characterize the population in our geographical area. In conclusion, we could observe that the pregnant women motivations for the use of a mobile application during pregnancy are highly concordant with those described in the reference paper [1]. This allowed us to define the functionalities to develop a mobile application for pregnant women within the HIBA PHR.

Operational Data Model Conversion to ResearchKit

Iñaki Soto-Rey, Sophia Geßner, Martin Dugas

Institute of Medical Informatics, University of Münster, Germany

Abstract

The increasing use of electronic health information systems brings up an unresolved issue: the lack of interoperability between these systems. The Clinical Data Interchange Standards Consortium’s Operational Data Model (ODM) is an xml based standard for the exchange of clinical data and metadata. The University of Münster has been using ODM to store medical forms in a web based metadata registry called Portal of Medical Data Models, which includes a complete set of tools to transform ODM forms into other formats. One kind of medical form is the Patient Reported Outcome, a trending type due to its ease integration with mobile data capture systems. ResearchKit is a development framework that allows the easy creation of these for iOS devices; unfortunately its current interoperability is limited. This research proposes a mapping between ODM and ResearchKit and presents the successful implementation of a converter for ODM into JSON based ResearchKit readable files.

Keywords:
Patient Reported Outcome Measures, Metadata, Health Information Systems.

Introduction

With the increase of electronic health information systems (HIS) in place, a problem arises: the interchange of information between these, formally called “interoperability”. This is still one of the biggest issues in Medical Informatics despite of the several initiatives pursuing a solution [1]. One of the most recognised institutions working on this field is the Clinical Data Interchange Standards Consortium (CDISC), a non-profit organisation which aims to enable HIS interoperability through vendor-neutral, platform-independent and freely available data standards [2].

The CDISC Operational Data Model (ODM) proposes a format for exchanging and storing clinical data and metadata. This xml based standard is compliant with the American Federal Drug Administration (FDA) submission guidelines for metadata [3]. ODM is widely spread and it is supported by numerous HIS. Hume et. al. reviewed 69 publications that describe several uses of ODM [4].

An example of the use and potential of ODM is the Medical Data Models (MDM) web portal1. The MDM project started in 2011 at the University of Münster with the purpose of enabling form based metadata exchange [5]. The web based portal developed by the Münster team contains, to date, more than 250,000 items encapsulated in more than 10,000 ODM medical forms, together with the so-called “ODMtoolbox”, a set of tools to generate, modify and transform ODM forms. The portal allows users to easily visualise, rate, comment and download medical forms, originally created, semantically annotated (using Unified Medical Language) and stored as ODM XML files, in several languages and formats such as PDF (with and without comments), CDA, CSV, FHIR (as JSON and XML format), Macro-XML, REDCap, SQL, SPSS, ADL, R and XLSX [6]. Furthermore, the portal also includes tools such as the so-called “ODMEdit”, a tool to create medical forms in ODM; once the forms are created, they can either be downloaded or directly uploaded to the MDM portal [7] and the “ODMSummary”, which allows the comparison of multiple semantically anotated medical forms in a web based tool with a high usability score [8]. In constant evolution, new forms and functionalities are regularly being included to the MDM portal, which became in 2015 the world’s largest open-access metadata registry.

One popular type of medical form are Patient Reported Outcomes (PROs), defined by the FDA as “measurements of any aspect of a patient’s health status that come directly from the patient (i.e., without the interpretation of the patient's responses by a physician or anyone else)” [9]. PROs are useful for the better understanding of clinical cases and the detection of patients’ life quality issues, but their use and interpretation must be carefully handled [10]. Regarding their benefits for clinical research, PROs have proven to be helpful when assessing patient trial eligibility and the efficacy of new treatments and therapeutic procedures [11]. Traditional paper based collection of PROs is though cumbersome and prone to error when, for example, the collected data needs to be manually introduced in a HIS.

Electronic HIS and especially mobile based HIS offer a great opportunity for the collection of PROs. Electronic PRO systems (ePROs) lead to more accurate and complete data, improved protocol compliance, avoidance of secondary data entry errors, easier implementation of skip patterns, less administrative burden, high user acceptance, reduced sample size requirements, and potential cost saving when compared to paper based collection of PROs [12].

As several ePROs are being developed around the world, the second most important mobile device operating system after android, iOS [13], has started its own initiative to support the creation of new ePROs with a development framework: ResearchKit2 (RK). RK allows developers to easily create ePROs with a standard user interface, optimised for all iOS based mobile devices. RK can be freely downloaded from GitHub3 (an online repository for open source projects) [14] and built with Xcode4. RK supports not only the collection of classic PROs containing traditional PRO questions (multiple choice, free text, numerical, etc.) but also other functions like a utility to provide information about the study and give consent re-

1 http://medical-data-models.org/
2 http://researchkit.org/
3 https://github.com/
motely; or information collection from several tasks available in mobile devices such as location, reaction time, balance, distance walked and multi-media records (audio, photo and video). These innovative measurements open a new spectrum of possibilities for clinical data collection and research, some of which are already starting to be used in clinical studies [15].

Unfortunately, the current version of RK does not support clinical standard formats, which hampers the exchange of information with other systems and the automatic inclusion of PROs, by for example re-using medical forms from repositories such as MDM.

The purpose of this research is to investigate the feasibility of a transformation from ODM forms into RK questionnaires and the development of a converter between these two formats, which should be integrated within the ODMToolbox of the MDM portal.

Methods

The first step was the investigation of the RK application programming interface (API) and the suggestion of a mapping between ODM and RK. For this, the ODM 1.3.2 specification was taken as reference and a list of the elements conforming ODM’s hierarchy was built. With this list, matches for every element were defined based on RK’s API and the RK items best representing ODM’s attributes and classes were listed next to their ODM homologs.

The second step involved the development of the ODMtoResearchKit converter, which was fulfilled using Java programming language and NetBeans as integrated development environment. During the development, some of the initially suggested mapped items were corrected.

The versions of the standard and software supported by the converter are ODM v1.3.2 and RK on its last update on GitHub (to date 853 forks), together with AppCore (81 forks), a model built on top of RK that includes important features not initially included in RK such as: dashboard with progress graphs; data storage back end; JSON serialization and deserialization and integration with Sage Bionetworks’ Bridge service [16]. For the manipulation of ODM forms, a Java library developed by the University of Münster in 2014 was used [17]. This library allows users to generate an ODM Java object from an XML based ODM form, which facilitates its manipulation with a Java based program for its conversion into other formats.

The functionality tests were performed using ODM samples from the MDM portal, converting them into RK JSON and importing them with the sample application available in RK’s API and the RK items best representing ODM’s attributes and classes were listed next to their ODM homologs.

The RK question types not visualised in the table and the ODM elements marked with “Not applicable” could not be mapped and will be analysed in the discussion.

The result of the mapping between ODM forms and a RK based questionnaires can be visualised in Table 1.

5 https://netbeans.org/
6 http://apps.icahn.mssm.edu/asthma/
The converter developed contains two main functionalities: One enables users to upload an ODM file in a very basic webpage deployed locally using Tomcat. This basic system imports the (ODM) file and generates a JSON file that is stored locally and visualised on the webpage. This functionality was mainly developed and used for local tests. The second and main functionality is the integration within the previously introduced ODMToolbox of the MDM portal. Figure 1 represents the common workflow to use the ODMtoResearchKit converter: (1) A registered user of the MDM portal searches for a desired medical form using the MeSH-based MDM searching tool and accesses to the form. (2) The user hovers over “Download” on the left part of the display and selects “ResearchKit (JSON)”. The downloaded .zip file contains the medical form in RK JSON format, as well as the license information and a JSON document with the form’s metadata. (3) The user copies the downloaded form into the resources folder of the RK-based ePRO and includes the file in the source code.

![Figure 1 – Process steps to be followed in order to find a desired data model in MDM, download it in RK JSON format and include it in a RK-based ePRO.](image)

The ODM to RK converter generates JSON files with a structure readable by any application that includes both RK and AppCore (Figure 2). In RK JSON, a questionnaire is defined as a task (RKTask). A task includes one to several questions named “steps”, as well as an identifier and a name. The steps are defined as single JSON objects and are encapsulated in a JSON array. Every step contains an identifier, a question text and an answer format and, depending on the answer format, other elements such as range limits for numerical questions or answer choices for multiple answer choice questions. It is also possible to decide whether a question has to be answered or not with the option “optional task”, which can also be imported from ODM’s “mandatory” field.

![Figure 2 – Example of the first question and three first answers of the Well-Being Index questionnaire in ResearchKit JSON format, generated using the developed converter.](image)

As RK does not support multilingual questions yet, the language of the items converted from MDM portal into RK JSON files will be the language selected for the visualisation of the form in the MDM portal. Multilingual functions for RK have been suggested and are part of the development roadmap.

The converter was positively tested using several PROs contained in the MDM portal, downloading them as RK JSON files and importing them with Asthma Health, a RK-based application available online, that includes AppCore to import RK JSON files [18].

**Discussion**

The converter developed is able to generate RK readable JSON files from an ODM file. With this tool, the more than 130 PROs and 9,000 medical forms available in the MDM portal can be easily downloaded and imported by RK-based apps. Besides, the test suite server developed is useful for local functionality testing and could be re-used by future converters.

Some limitations need to be pointed out: RK does not include or use a standard for using medical forms; it just provides a framework that facilitates the development of new ePROs. Thus, a mapping between ODM and the RK questionnaire structure is not straightforward. Likewise, ODM is not PRO oriented and it does not include some useful question types supported by RK.

These are the ODM item types not supported by RK:
- hexBinary | base64Binary | hexFloat | base64Float
- partialDate | partialTime | partialDateTime
- durationDateTime
- incompleteDateTime | incompleteDate | incompleteTime
- URL

RK question types not supported by ODM:
- ContinuousScale

---

• Email
• HealthKitCharacteristicType
• HealthKitQuantityType
• Location
• TextScale
• Multi-media (Audio, video and photo)

Together with the activities supported by RK (and not by ODM):

• CountdownStep
• Fitness
• TowerOfHanoiStep
• WalkingTask

ODM v1.3.2 includes a possibility to represent multiple-choice questions using code lists. On the other hand, it cannot be defined if several of the choices contained in a code list could be answered. This represents a limitation when converters from ODM metadata into PRO based formats are developed, as it is an essential characteristic of classic PRO questionnaires. In practical terms, this means that a conversion between ODM and PRO formats requires post-conversion handling for this kind of questions.

RK is meant to be used by ePROs created for a single study. Thus, an element that represents a study within the JSON structure is not needed (as there will only be one). ODM on the other hand, includes a great amount of information about the study that, due to RK’s limitation, will be lost when generating RK compliant JSON files with this converter.

RK includes mainly user interface capabilities; it needs AppCore for useful features such as serialisation and deserialisation of JSON files. Although AppCore functionality is soon to be included in RK, to date, a RK-based ePRO would need AppCore in order to import JSON based questionnaires.

There are several systems available for the electronic collection of PROs. The most simple ones are electronic online survey systems such as LimeSurvey [19], which offer a wide variety of languages and configuration options for the easy creation and customisation of surveys, but are normally just used for anonymous collection of simple data as data privacy may be an issue. Other systems are also multi-language and web-based, but are so far only developed to be used in a clinical setting, restricting their use with the a web clip installed in a mobile device [20]. Some other ePROs just provide an application developed compliant with several operating systems and devices, but they are normally developed for a single purpose [21], [22]. Another notable exception is REDCap: a methodology and a software solution for the rapid development and deployment of electronic data capture tools to support clinical and translational research though intuitive electronic case report forms and metadata import functions [23]. Other projects like C3PRO propose a working framework for the exchange of information between ePROs and different HIS though medical standards [24], but they are focused on clinical data, and not on metadata and import of medical forms. The great availability of systems in place should be taken into account when a new one is requested.

RK is only compliant with iOS devices. Another project that uses RK as basis and provides a similar framework for Android devices is ResearchStack8. We decided to develop firstly the ODM to RK converter, since RK represents the original framework compared to ResearchStack. Furthermore there are currently more initiatives using ResearchKit to conduct research and, most importantly, after a short look into ResearchStack’s source code, one can observe that ResearchStack has preserved RK’s structure and functionalities which suggests that the JSON files generated by the OD-MtoResearchKit converter could also be importable by ResearchStack based ePROs.

Electronic PROs have surpassed the possibilities of PROs. Modifications on traditional PROs should be considered so that they include new question types and tasks available only on electronic devices (previously mentioned). To the knowledge of the authors, there are no official guidelines for these question types and tasks to be included as part of PROs yet. Likewise, ODM should include some of these useful question types and tasks in order to update it to the new ePROs, as well as a solution for the multiple choice questions previously explained. RK should consider the possibility to select a different graphic interface and survey languages. As soon as this functionality is available, a small update on the ODMtoResearchKit converter needs to be carried out so that the JSON files generated contain the elements in various languages. The MDM portal contains, to date, more than 130 PROs. This number is thought to be low compared to the total amount of data models included in the portal. The most important reason for this is the lack of licence free PROs. A feature to include non-licence free PROs in the MDM portal could be developed so that only users with rights to use these kind of PROs could download them. The converter could be enhanced with a library to manipulate RK objects in Java, which would facilitate the export in different formats (swift or objective-c code for example) and further tests are needed to demonstrate the compatibility with ResearchStack.

Conclusion

A mapping between ODM and RK questionnaires was suggested and a converter for ODM forms into RK readable JSON forms developed. With this converter integrated within the MDM portal, more than 130 PROs and 10,000 medical forms contained in it can be easily imported by RK-based ePROs. Further work should include a Java based RK questionnaire library and tests to demonstrate the generated JSON files’ compliance with ResearchStack.

A Secure Architecture to Provide a Medical Emergency Dataset for Patients in Germany and Abroad

Abstract

The ongoing fragmentation of medical care and mobility of patients severely restrains exchange of lifesaving information about patient's medical history in case of emergencies. Therefore, the objective of this work is to offer a secure technical solution to supply medical professionals with emergency-relevant information concerning the current patient via mobile accessibility. To achieve this goal, the official national emergency data set was extended by additional features to form a patient summary for emergencies, a software architecture was developed and data security and data protection issues were taken into account. The patient has sovereignty over his/her data and can therefore decide who has access to or can change his/her stored data, but the treating physician composes the validated dataset. Building upon the introduced concept, future activities are the development of user-interfaces for the software components of the different user groups as well as functioning prototypes for upcoming field tests.

Keywords:
Emergency treatment; Emergency Service, Hospital; Health information exchange

Introduction

Due to increasing specialization and fragmentation of medical care, as well as an increased mobility of patients, the information flow, which enables a fast exchange of lifesaving information about a patient's prior medical history, is significantly hampered [1,2]. Especially in cases of emergency, where the patient is possibly unconscious and cannot be asked about previous illnesses or current medication, this information can be exceedingly vital [2,3].

To establish an environment of quickly accessible patient information in case of emergency, many countries have started to implement or plan to implement Medical Emergency Datasets (MED). Scheduled for 2018, the German Electronic Health Card (EHC) is supposed to hold a MED [4,5,6]. Authorized health professionals (e.g. primary care physicians) are asked to create these datasets, if requested by the patient. Vital information about previous diagnoses, medications, allergies and other emergency-relevant information are stored on the card [5,7]. Additionally, the patient has the opportunity to save information about the locations of important personal statements such as organ and tissue donor ID, end of life decision or a power of attorney regarding medical care.

Against the background of this upcoming implementation, the German Medical Association [8] and the University Hospital Muenster have conducted a validation study in 2014, which surveyed the usability, the necessary instructions as well as analyses on the expected usefulness of paper-based MEDs. Results indicate that the questioned medical personnel, who included emergency physicians, clinicians and paramedics, see MEDs as very useful or useful. Specifically, preliminary diagnoses and medications were rated as highly relevant for the emergency care [9]. Building upon the aforementioned findings, the pilot study ‘NFDM-Sprint’ is currently in progress, which is concerned with analyzing and optimizing the creation process of MEDs. During the study, MEDs were created by physicians and evaluated by the researchers. The results of the study are pending at this time.

With regards to the technical solution in accessing MEDs on the EHC in Germany, decryption of the stored data will only be possible with an electronic health professional card. Accordingly, this restriction will limit the access to the MED to Germany only [10,11]. When individuals are traveling to foreign countries, local health professionals cannot access the data. Furthermore, only publicly insured patients will have the opportunity of storing a MED on their EHC, since the EHC is not issued to privately insured patients.

In March 2016, the three-year project Timely Information in Medical Emergencies (T.I.M.E.) started its research in the field of emergency care. The project is funded by the European Union and the Federal Ministry of Health, Equalities, Care and Aging (MGEPA) of North Rhine-Westphalia. Confronting the expected limitations of the upcoming MED implementation, one of the project objectives is to expand the previously defined concept of MEDs by emergency-relevant findings and documents. The main goal is to offer an alternative secure technical solution for a widened access to emergency-relevant information via mobile accessibility and to test and evaluate a functioning prototype to proof the concept. Additionally, a solution for the access to MEDs abroad is being investigated. Final discussions with the Commissioner for Data Protection of the federal state of North Rhine-Westphalia are currently in progress to finalize the data protection and privacy concept, which makes the architecture prone to minor changes. The goal of the current work is to describe the conceptualized software architecture.
Methods
Firstly, unstructured interviews with domain experts were conducted to determine which information should be provided with an enhanced MED and how it can be administered and retrieved. Based on these interviews use cases describing the requirements were defined. Secondly, the preexisting data model of the emergency dataset for the EHC developed by the German Medical Association and gematik [12], the Society for Telematics Applications, which is mandated to carry out the introduction of the electronic health insurance card, was taken as a basis and an extended data model containing all relevant data from the interviews was derived. Thirdly, a concept fulfilling pre-defined use cases and the provision of an emergency dataset for patients in case of emergency was created. Finally, a data protection and privacy concept was developed and discussed with the Commissioner for Data Protection of the federal state of North Rhine-Westphalia.

Results
Use Cases
At first the requirements given by domain experts were formalized in four use cases:
- Authorizing the access to the emergency dataset by the patient
- Creating or updating an emergency dataset by an authorized physician
- Reading the emergency dataset in case of emergency in Germany
- Reading the emergency dataset in case of emergency in a foreign country
The four use cases address the central requirements, which are data security, creating and updating the MED and the procedure in case of an emergency in Germany and abroad.

Medical data model

![Image](image_url)

**Figure 1** – Overview of the Patient Summary for Emergencies

As shown in Figure 1, based on the MED developed by the German Medical Association and gematik for the EHC, an enhanced dataset was developed. The Emergency Data Management Concept developed by gematik consisting of contact data (CD), MED and personal statements of the patient (PSP) was not altered significantly to ensure interoperability with the emergency dataset on the EHC. Additional information, for example, imaging and laboratory findings were added to the dataset under the heading ‘Emergency-relevant findings and documents (EFD)’, to provide comprehensive information for the practicing emergency physicians. Thus, information like X-rays and physicians’ letters stored in formats like images or PDF documents can be made available for the emergency physician. In summary, all this information is stored in the Patient Summary for Emergencies (PSE).

Figure 2 shows the detailed data model of the EFD. Every finding in the EFD has corresponding finding documents and will be created by an identifiable treating physician or institution. The treating physician, who decides which information is added to the current EFD, is also documented as the administering physician of the findings in the EFD, as given in the national MED.

![Image](image_url)

**Figure 2** – The medical data model of the emergency-relevant findings and documents

Concept
CompGroup Medical (CGM), the market leader for physician information systems in Europe, will develop the prototype. The existing infrastructure and components of CGM will be used for the implementation. Nevertheless, the concept can be generalized and developed in the same manner by other manufacturers.

As seen in Figure 3, the central component of the system is an electronic patient record called PSE, which stores the enhanced MED. All information stored in the PSE is encrypted with state of the art encryption algorithms and can only be accessed by authorized users. The authorization to access, change or add data in the record is managed by the patient him- or herself.
Authorizing the access to the emergency dataset

The system is patient-centered, which means the data is stored, altered and accessed only with explicit permission given by the patient. For the creation of the PSE, the patient has to give informed consent in written form to the physician, who creates the PSE within the patient record.

Medical professionals have to be registered with their official profession within the system, like first responder or emergency physician, to access the PSE. To enable medical professionals to access the PSE, the patient can generate an access token within his/her patient portal, which is a string consisting of 25 characters. This access token can be obtained as a Quick Response Code (QR-Code), which can be opened by a preinstalled app showing the released data from the PSE. If the app is not installed an error is shown. Thus, a two-factor authentication is established. Table 1 shows the standard authorization configuration for a released PSE. The first aiders, who are defined as nonprofessional helpers like people seeing an accident and initiating an emergency call, are not granted access to the data if they scan the QR-Code. However, if a registered medical professional like the emergency service or the emergency physician uses the QR-Code, he/she can retrieve appropriate medical data regarding their needs for the emergency.

Reading the emergency dataset in case of emergency

Registered medical professionals like the emergency service or the emergency physician can retrieve the PSE. The registration can be done by the medical professional him/herself using the health professional card or by an authorized organization like the German Medical Association or aid organizations, who can proof the accreditation of the medical professional.

After the patient has released the PSE, he/she can print the corresponding QR-Code for the created access token. In case of emergency, the medical professional may scan this QR-Code and can retrieve the appropriate information as shown in Table 1 (C in Figure 3). The patient will be notified about every data access by other users through the patient portal and the QR-Code will automatically be disabled after a predefined period of time. Thus, the data cannot be retrieved for an unlimited time afterwards and the patient has to create a new access token to re-enable the access to the PSE. Therefore, the patient is responsible for updating the access token and carrying along the current active access token to provide access to his/her emergency dataset.

Since the expertise of health professionals in foreign countries cannot be verified, as there is no global health professional card or a standardized way to identify health professionals, the access to the PSE has to be achieved differently in foreign countries. In case of holidays or business trips, the patient has the opportunity to extend the access rights to the PSE for a specified period of time. Thus, anybody who scans the QR-Code within the specified period of time can access the whole PSE without any authorization mechanisms in place.

Data privacy and data protection

The stored information in the PSE is encrypted with state of the art industrial standard encryption algorithms. It is therefore not possible to decrypt the information with reasonable effort, without knowledge of the secret private key. Moreover, the communicated data is end-to-end encrypted and the communication between the system, which runs the PSE and the client devices is encrypted as well.

Creating or updating an emergency dataset

The creation (A in Figure 3) and update (B in Figure 3) of a PSE is done exclusively by an authorized physician, as only a treating physician who knows the patient can determine which information is useful in case of emergency and should be part of the PSE. Only contact data and information regarding personal statements can be updated by the patient (Figure 3, bottom right corner), but he/she is not allowed to create a PSE. On the one hand, the physician can use an integrated form in his/her physician information system to manage the PSE (Figure 3, top left corner). On the other hand, he/she could use a web portal developed for physicians who do not have physician information systems or use a physician information system without PSE integration (Figure 3, bottom left corner).

Since the physician decides which information is relevant for the PSE, the patient cannot choose if specific medical information from his or her medical history or current illnesses is present in the current dataset. Thus, the PSE will always be a valid set of medical data approved by a physician. After creation or update of the PSE, the patient is notified about the changed data. Until the patient releases the new PSE or revokes his/her participation, the outdated PSE is not available in case of emergency. As the updating process is during the consultation with the physician, the time gap between an outdated and confirmed PSE should not be too long. However, the patient can revoke the permission to store the PSE at any time. If he does so or does not give his permission after an update, his complete PSE will be deleted. It is therefore an all-or-nothing approach. Since the emergency data of the patient will partly be stored on the EHC in form of the MED, the system will integrate a mechanism for updating the data on the EHC and updating the data in the PSE from the EHC.
The personal and medical information of the patients are only temporarily stored on the clients’ devices. After closing the app but at the latest after three hours the data will be deleted. Furthermore, the app checks if the device has been rooted or jailbroken, which leads to an error and closing the app. The access to the patients’ data is managed by the patient him-/herself and the patient has the opportunity to revoke the consent on storing information in the PSE and to delete the information stored in the PSE at any time. The patient is notified every time his/her information is changed by a physician and he/she has to approve the new emergency dataset.

An audit trail for all accesses to the PSE is stored, so the patient is able to see who has accessed his/her medical information and when it happened. Furthermore, an encrypted snapshot or screenshot of the viewed data is stored within the PSE to provide the opportunity to notice abuse of information or for legal reasons.

Discussion

The objective of this work was to illustrate a software architecture for a secure technical solution to make an extended MED available to users via mobile accessibility in Germany and abroad. Built upon the current version of the official German MED model, the presented concept shows an alternative way of getting emergency-relevant information to medical professionals directly to the emergency site. The PSE, containing the Emergency Data Management components and additional emergency-relevant findings and documents, builds an enlarged basis for diagnostics and forms the foundation for this enhanced software solution. The current concept offers a way for secured access to the data via a two-factor authentication (QR-Code plus app). Only medical professionals registered within the system with their official profession, like first responder or emergency physician, are allowed to access the PSE to retrieve appropriate medical data regarding their needs for the emergency. Due to more information about the patients’ medical history, the physician gains greater knowledge of patients’ clinical characteristics and this is expected to improve medical decision-making [13].

To get overall clinical acceptance of the PSE, it is essential that the quality of data be guaranteed. A possible way in achieving this is if the treating physician is also the administrator of the PSE. Nevertheless, the patient could also provide additional information during the creation of the dataset since he/she can be asked specifically about emergency-relevant findings assessed by other physicians.

Concerning the limitations of this study, the PSE will exclusively be tested using the existing infrastructure and components of CGM. However, given the plans of the government for building a healthcare telematics infrastructure which includes the provision of MEDs to the public by 2018 [6], transferability of the concept to other systems has been the focus of this project from the start.

Since the PSE is primarily meant to be accessed at the site of an emergency, mobile Internet access is a vital requirement to be able to get the crucial information. Restrictive factors of mobile Internet access are of course still present in form of data volume limitations or areas with no connectivity, yet a comprehensive network covering the area of Germany is scheduled for 2018. Another factor that has to be accepted is that a mobile device, seen from the point of information security, has a residual risk of exploitation. To minimize the risk the delivered app will check the device for roots and jailbreaks. However, since emergency-relevant data should be available quickest possible, the access via mobile accessibility is crucial. Still, the patient has to be informed about all possible security weaknesses and has to give informed consent acknowledging these data privacy concerns. Furthermore, a privacy issue regarding accessibility of MEDs abroad might be raised, as for a defined period of time no authorization mechanism would take place when scanning the QR-code, giving access to sensitive data. This concern is a prominent discussion point in the ongoing developmental process of the concept and has also been stressed by the Commissioner for Data Protection of the federal state of North Rhine-Westphalia. While it can be argued that a patient has the sole responsibility for the safety of the QR-Code when being abroad, two alternative data protection solutions with controlled activation are currently being discussed. Firstly, a call center can grant access to the PSE to the emergency physician, after verification of the physician’s profession. Secondly, implementation of a two-factor authentication sending a short message to the patient or a relative to acknowledge the access to the PSE could be an option.

Next to the limited authentication measures abroad, another issue is the translation of the content to another language. Since the dataset offers free text fields without proper semantics, automatic translation cannot be provided at this point. Furthermore, Germany has not licensed the international terminology SNOMED CT [14], which could have been used to achieve semantic interoperability. Nevertheless, the PSE will partly be mapped to international terminologies and classifications, like the International Classification of Diseases for diagnoses, Logical Observation Identifiers Names and Codes for laboratory values and Anatomical Therapeutic Chemical Classification System for medication. Additionally, there are initiatives that promote cross border exchange of personal health data like the pilot project Smart Open Services for European Patients (epSOS) [15], a six-year initiative which ended in 2014. In the project, regulatory, technical and organizational aspects were Blueprinted for a cross boarder electronic health record system including the healthcare services ‘electronic Prescriptions’ and ‘Patient Summaries’. While there are strong content-related similarities between the epSOS Patient Summary and the official German MED, the primary application area of patient summaries is in doctors’ offices or hospitals. Consequently, the use of this data sharing approach is not applicable at the emergency site.

To overcome the interoperability issues, the development of an international profile, like IHE XDS, specifically addressing the emergency dataset, should be considered. Furthermore, the introduction of an international electronic health card for all citizens and an international health professional card for medical professionals would be helpful for exchanging health data and authorizing the access to health data [13].

Conclusion

In conclusion, a concept for a secure architecture to provide a medical emergency dataset for patients has been proposed. With the implementation of this architecture in its finalized state, it will be possible to supply medical professionals with emergency-relevant information concerning the current patient via mobile accessibility. Furthermore, the patient will have the opportunity to use his/her emergency dataset not only in Germany but also whilst travelling abroad.

The next activity in the T.I.M.E. project is the development of user-interfaces for the software components of the different user groups. Using these proposed user interfaces an online survey among physicians will be conducted to determine the optimal user interface for displaying MEDs. Based on the results of the survey a functioning prototype will be developed, tested and
evaluated. Finally, a support infrastructure (e.g. telephone hotline) has to be constructed for the test phase and possible future commissioning.

Abstract

Despite the increasing adhesion of electronic health records, the challenge of semantic interoperability remains unsolved. The fact that different parties can exchange messages does not mean they can understand the underlying clinical meaning; therefore, it cannot be assumed or treated as a requirement. This work introduces an architecture designed to achieve semantic interoperability, in a way which organizations that follow different policies may still share medical information through a common infrastructure comparable to an ecosystem, whose organisms are exemplified within the Brazilian scenario. Nonetheless, the proposed approach describes a service-oriented design with modules adaptable to different contexts. We also discuss the establishment of an enterprise service bus to mediate a health infrastructure defined on top of international standards, such as openEHR and IHE. Moreover, we argue that, in order to achieve truly semantic interoperability in a wide sense, a proper profile must be published and maintained.

Keywords:
Electronic Health Records; Health Information Exchange; Vocabulary, Controlled.

Introduction

Different systems are said to interoperate when they can provide an expected functionality on top of a common interface. Narrowing the context to electronic health records (EHRs), a common way to label interoperability relates to its depth [10]: syntactic, functional or semantic, according to whether the message is properly parsed by machines, humans or both. Keeping that concept in mind, this work tackles the current lack of interoperability, a major barrier in current medical systems.

There are a few suggested approaches in the known literature. Ryan and Eklund [6] coined, several years ago, the idea of the Health Service Bus (HSB), acting as a middleware that routes and transforms services, in order to mediate interactions with a common infrastructure. However, the described approach is cumbersome and hard to maintain. We argue that, instead of a translation approach, it is more suitable to build a future-proof architecture from the ground up.

Despite the availability of some quite respectable references when it comes to establishing a wide e-health strategy [9], if we take a look at the Brazilian scenario, it is easy to identify a silo architecture, inherited due to the compatibility with legacy systems. At this point, not only are the services coupled, but the implementation is also tied to the data persistence mechanism. This leads to a problem-oriented architecture that makes semantic interoperability practically unreachable.

On the other hand, replacing an architecture implies great effort and requires strong reasons. Current scenarios usually focus mostly on administrative and financial data, providing poor clinical value. This is a problem that also needs attention. After all, if we are looking to a more appropriate solution, this is also the opportunity to improve the quality of healthcare. This work is driven towards a reference architecture, wherein it is extremely important to prioritize the knowledge artifacts. Nonetheless, in order to present a future-proof solution, a mature and self-contained theoretical proposal is desired. This is why our work is built on top of international standards such as IHE [2] and openEHR [1]. Although this combination is not new to the literature [5; 7], the known texts lack functions vital to semantic interoperability, such as mapping terminologies [4]. Other aspects, such as identity management, consent, security and privacy also apply, but are out of the scope of this paper, even though they share the same principles summarized here with a common goal: to facilitate the access to healthcare data.

This project is supported by the Hospital Alemão Oswaldo Cruz through the PROADI-SUS program, a governmental initiative that encourages excellent hospitals to propose and execute projects within topics defined by the Ministry of Health. Moreover, it is quite beneficial that we can implement this design in a controlled region, while still interoperating with other parties in a way that it can coexist or expand nationally.

The next sections are organized to first introduce our methods, which are the standards and techniques orchestrated to compose the solution, followed by the resulting architecture, a discussion of the contribution to the current scenario and the conclusions.

Methods

This section details the building blocks of the architecture, built on top of international standards. The main goal we introduce is to achieve EHRs that both machines and humans understand. As for the first part, the IHE standards provide a quite solid specification for distinct health organizations to exchange data, tackling syntactic interoperability. When it comes to semantics, even though solutions such as openEHR already take a step further in bringing meaning into messages, there are pitfalls, e.g. terminology mapping and management of clinical artifacts.

IHE

When we defined interoperability, one of the key points was to be understood by a machine. This is exactly where Integrating the Healthcare Enterprise (IHE) steps in, introducing an IT infrastructure framework described by a set
of profiles that standardize all the defined transactions between the actors, including the messages exchanged.

**Profiles**

As stated, IHE standardizes transactions in a way that they can be processed by the machines. The guidelines are published and maintained within modules known as profiles. There are various profiles, but a few ones are listed below:

- **ATNA (Audit Trail and Node Authentication)**: security measures, data integrity and accountability;
- **CT (Consistent Time)**: time synchrony between multiple actors and computers;
- **XCA (Cross-Community Access)**: query and retrieve medical data within other communities;
- **XUA (Cross-Enterprise User Assertion)**: communicate identity claims in transactions that cross affinity domain boundaries.

There are also three more profiles (PIX, PDQ and XDS.b) highly important to this discussion. They will be discussed next.

**PIX**

The Patient Identifier Cross-Referencing (PIX) profile provides a mechanism to correlate patient identifiers from different domains in a common module. It provides not only querying and retrieval of identifiers, but also a feed notification, so that other actors can react immediately to related events.

**PDQ**

Somewhat related to PIX, the Patient Demographics Query (PDQ) profile allows an actor to resolve identities based on demographic information. It also allows the system to customize the level of exposure, controlling the amount of demographic information shown and the associated input filters.

**XDS.b**

The Cross-Enterprise Document Sharing (XDS.b) is the most relevant profile when it comes to syntactic interoperability and describes two important actors within our architecture: the document repository and the metadata registry. It is based on the OASIS ebXML specification, the de facto standard for interoperability of content through standardized transactions. The document repository acts as a distributed document database, serving the exchanged documents.

The metadata registry is unique. It catalogs a set of metadata for each document available across the system, indexing submissions coming from different repositories. The community established around a registry is called an “affinity domain” in the IHE vocabulary.

Every interaction within an IHE actor happens through a well-defined transaction, commonly denoted by ITI-n. For example, ITI-41, ITI-42, ITI-18 and ITI-43 refer to submitting, registering, querying and retrieving documents, respectively. More information is available in the referenced documentation.

It is important to notice that the XDS.b is an integration profile, completely neutral when it comes to the document contents, which is why we say it contributes to syntactic interoperability.

**openEHR**

Taking a step further into the goal of semantic interoperability, openEHR is defined as a domain-driven platform for e-health. It is actually a dual-layer approach that introduces a new way of modeling knowledge artifacts.

Beale et al. [1] argue that interoperability is difficult to achieve because common single-model systems use different models. This is how openEHR stands out.

**Reference model**

The bottom layer is the reference model, a set of stable specifications at the core of the data layer that provides a finite number of data types and structures to be processed by the platform during compilation time.

**Archetypes**

Upon the bottom layer, there is a top one that deals with organic units of information, usually known as archetypes, at runtime. The advantage of such an approach is that archetypes can be maintained by domain specialists, without the need to deal with complicated languages or technicalities from the bottom layer, following the principle of separation of concerns.

We can think of an archetype as a serialization of a structured information tree, wherein the upper nodes are use cases customizable according to specific business needs and the leaf nodes are classes formally defined within the reference model.

**Templates**

As defined by openEHR, an archetype is supposed to be an organic unit of clinical information, such as blood pressure, to be reused in different contexts.

In order to achieve something closer to a clinical encounter, openEHR allows compositions, normally known as templates, to be outlined as a combination of archetypes with equivalent or narrower restrictions related.

From a computer science perspective, this actually states that an archetype in a template is a subclass of its parent definition, stating an inheritance relationship wherein the child can be seen as a valid instance of the parent, e.g., backward compatibility.

Revisiting our tree analogy, the template is the root and each of its subtrees configures an archetype developed and used locally.

**CTS2**

ISO ANSI [3] clarifies that semantic interoperability is not binary. There are degrees depending on the level of agreement on ontology, which is why in our work the terminology server is independent and self-centered.

The Common Terminology Services 2 (CTS2) is a specification resulting from extensive work by both HL7 and OMG. On top of authoring and serving code systems and value sets, the key definition is that the terminology server is able to translate concepts on machine and human domains, e.g., code and terms.

We also have to take into account that different health professionals may have distinct ontologies in their own domain. It is expected that such associations can be mapped and reproduced as knowledge, regardless of how the data is stored, so that it is also possible to have different terminologies when creating and retrieving a document, depending on local needs.

**SNOMED CT**

When we bring to the table the mechanic linking of ontologies, it is common to question the weight of a single terminology. However, a reference is still needed, so that all the mappings refer from or to this major set of clinical terms.
SNOMED CT [8] is the most comprehensive and precise clinical health terminology product that we are aware of. Therefore, it is the elected reference ontology, so that the community itself can act on mapping a local terminology in a way that it becomes available and understandable for others. This can be done directly in the CTS2 module, wherein such mappings go through a formal governance, or more loosely on an openEHR document, wherein local mappings can be documented and later collected as an incoming data set to be processed by the backend itself.

**Results**

In this section, we demonstrate the consolidated architecture. First, we start with a general overview of the Brazilian HSB, then we highlight several interesting aspects.

**The Brazilian Health Service Bus**

The core proposal of this work is the design shown in Figure 1. We propose an Enterprise Service Bus (ESB) to serve vendor-specific implementations behind the standard contracts, defined by IHE. The document repository and metadata registry interoperate with an existing PIX/PDQ layer, which is, in turn, connected to a Master Patient Index (MPI) infrastructure. So far, everything conforms to the IHE ITI Technical Framework. But now there are important additions: the CTS2 server and the Clinical Knowledge Manager (CKM) module, both exposed as services. They are expected to provide ontology mapping and knowledge artifacts, respectively.

While it is expected from the environment to somehow interoperate with the CTS2 and CKM services, such communication and governance schemes are not standardized. The resulting ecosystem relates not only the known IHE and openEHR organisms, but also actors related to knowledge artifacts governance, terminology mapping and access points. Therefore, although the document exchange and modeling are specified, this architecture also tackles the remaining gaps that prevent heterogeneous entities from sharing the infrastructure.

**Semantic interoperability**

ISO ANSI [3] identifies four prerequisites for semantic interoperability:

1. Standardized EHR reference model: comes from the openEHR reference model;
2. Standardized service interface models: while there is an ambition regarding the openEHR service model, currently in development, it is not wide enough for semantic interoperability. This work introduces an overview of the functional architecture, but the service interface models must be defined based on local needs;
3. Standardized set of domain-specific concept models: the openEHR archetypes and templates;
4. Standardized terminologies: SNOMED-CT is taken as the reference; archetypes and templates are free to bind according to specific needs, as long as the related mappings are available, relying on the CTS2 for that.

While we have discussed all of them, the practical contributions from this paper relate mostly to the composition of a standard service interface model and ontology resolution.

**Improvement of health care**

Not only is the proposed architecture built on top of recognized international standards, but it is also designed to be patient-centric. It is ready to facilitate access to healthcare data and also to take part in even broader e-health integration scenarios.

**Integration between health processes**

With the siloed architecture gone, we are ready to embrace a service-oriented architecture. All transactions drawn from IHE are inherited from ebXML, a mature set of enterprise standards.

**Decision support**

As soon as we reach the capability of semantic interoperability, it is finally reasonable to think about clinical decision support. Now that systems and people are able to exchange and understand the underlying clinical information,
practitioners can consume all healthcare data like a timeline, in such a way that it sets a full-featured EHR.

**Epidemiology and public health**
Considering that demographics and healthcare data are stored separately, it is now possible to compute statistics and population metrics. For example, by using AQL queries, we can select records based on contents and even reshape the document structure according to specific needs (e.g. big data and BI). Moreover, we can also idealize custom triggers that monitor and track the behavior of specific parameters within an observation range and fire customized alerts for health events.

**Federation**
Even though IHE states that the document registry must be unique within an affinity domain, we find it mandatory for distinct communities to be able to interoperate in a wider sense than specified by the XCA profile. Actually, our architecture is designed so that HSBS can be established as siblings (e.g. independent regional deployments aware of each other) while federated under a parent and eventually its ancestors (e.g. national deployment that catalogs all available health records). In other words, this work elaborates an HSB mature on its own but ready to coexist and federate.

**Discussion**
At this point of the document, we introduce new discussions that unfold from the current results.

**Service model and openEHR REST API**
With the openEHR clinical modeling features proven valuable, a lot of work from the openEHR Foundation emerged regarding a standardized REST API to handle knowledge artifacts. While it is likely not to replace the IHE layer, as such an approach to exchange data among parties is already in use by the industry, it can surely provide a more lightweight service interface that refines the granularity of the EHR to more specific levels, such as templates, archetypes and even data, instead of the document-oriented style from IHE.

With such developments in mind, it makes sense to have a dedicated openEHR server within the architecture, so that we have more than just documents, such as the Archetype Query Language (AQL), which enables us to operate on the models, instead of the serialized data itself.

On the other hand, as the openEHR REST API delivers functionality beyond the capabilities of the IHE specification, we already have an orchestration infrastructure to enable controlled usage, either internally or externally.

**openEHR and FHIR**
Fast Healthcare Interoperability Resources (FHIR) is a recent standard proposed by HL7 as an API to enable parties to exchange data, aiming for less complexity and more flexibility, especially when compared to HL7v2 and HL7v3 messages. It works upon the idea of resources and profiles, i.e. reference model and archetypes/templates within the openEHR scenario. Although not exactly the same, it is possible to translate them, so we can embrace an even more heterogeneous environment, and such an implementation design is suggested for parallel work.

**Management of knowledge artifacts**
Along with all the orchestration we have presented so far there is the assumption that the knowledge artifacts are reachable. This can get in the way of semantic interoperability, especially when different vendors coexist within the same infrastructure, because there is no standard way to manage archetypes and templates. The same goes for validating external terminologies.

That being said, there are several approaches going on, most lead by implementing vendors. Despite having, for example, a CTS2 standard to interoperate with a terminology server, we lack a formal definition of how an EHR would consume it. Additionally, within the openEHR context, there is the Clinical Knowledge Manager (CKM), a distributed portal do handle archetypes and templates encompassing a reasonable life cycle, including approval, translation and versioning of objects. However, again, there is no standardized way for one actor to interoperate with such functionality.

**Interoperability with different affinity domains**
Most of the solutions known so far assume a set of document repositories working together under the umbrella of a single metadata registry, which configures an affinity domain. On the other hand, the architecture we propose satisfies the possibility of multiple affinity domains coexisting in a federated fashion. Along with this scenario, new concerns about security and privacy emerge, demanding a more prolific governance profile.

**Future work**
Even though this architecture achieves the goal of exchanging understandable health data, there are important use cases other than immediate care that could be practical for further work. We discuss several topics below.

**Case management**
As soon as we have a good healthcare data architecture with basic semantics aiming for decision support, the spotlight moves towards workflow support.

The objective is to come up with a collaborative model capable of covering a whole episode, e.g. ongoing care and monitoring, different professionals and the social scenario of the patient. Besides the need to systematize medicine within protocols, it is also needed to formalize such concepts in a computable way that handles decision points with logic. Even at this point, as much as we translate care for conditions into protocols, care for a person may follow infinite paths because of many factors.

The openEHR bottom-up approach somewhat tackles decision support, starting with an extensible standard state machine to act like a GPS system, even capable of correcting wrong turns.

**Internet of things (IoT)**
Through the progress of the IoT, home and self-care devices will become popular quite quickly. However, there are several difficulties to be clarified. Above everything, we need a secure interface for those devices to aggregate data.

Not only is such data highly transactional, meaning it could flood an EHR with irrelevant or repetitive information, but also the responsibility for its accuracy is not clear.

**Secondary use**
Beyond the boundaries of primary care, secondary use implies extracting information not about the patient itself, but about the healthcare ecosystem instead.

Now that we have meaningful data in a structured way and detached from any demographic information, the idea of computing population statistics and triggering disease control programmatically becomes perfectly feasible, as long as...
maintainable policies regarding usage consent are available. The same applies for management and research.

It is important to acknowledge that the openEHR approach for querying and shaping EHRs as needed with AQL allows the processing of clinical data on a functional level of granularity, e.g. an archetype, regardless of the templates used to input data, relying on the object model instead of the serialized message. Moreover, range comparison, filtering and data sorting functions included with the querying language enable governments to compute over heterogeneous and huge datasets, feeding big data and business intelligence systems accordingly.

Conclusions

When it comes to health data, semantic interoperability cannot be achieved if systems using disjoint standards don’t cooperate.

Now, taking a step back in the discussion conducted so far, we built a complex architecture on top of the known IHE ecosystem, tackling a more complex situation wherein a federated infrastructure is expected to validate openEHR documents with bindings to external terminologies.

This work also elaborates on the management of knowledge artifacts, more specifically debating the usage of the CKM to handle archetypes and templates within a reasonable life cycle that makes sense to domain specialists.

At last, we pointed out the recent work on the openEHR REST API and introduced a possible compatibility path to expand our environment towards FHIR systems.

A new profile

A major observation presented here is the desire for further standardization in order to achieve semantic interoperability. The proposed architecture is a suitable starting point, wherein a reference organization such as IHE can elaborate in order to develop a more solid specification.

Several important requirements can be drawn from the gaps that our mediation is intended to overcome, namely:

1. Provide semantic meaning to the shared documents: IHE exchanges binary data with a MIME type and some arbitrary classification metadata, which is not enough for it to be processed as a true document by the recipient.
2. Allow consumers to map local ontologies as needed, reducing the impact for different entities to collaborate.
3. Allow consumers to locate and collect models and resources published by others that are relevant to handle instances of such data (e.g. archetypes and templates).
4. Specify a core set of features on top of the model itself, in order to prevent vendor lock-in.
5. Provide a standard for patients to manage consent and trace it along with their documents. Such information must be available within the infrastructure as well so that the policies can be enforced to exchange health data.

By satisfying the criteria described so far in this work, upcoming specifications are closer to achieving a semantically interoperable electronic health record wide enough to support an entire country.

Acknowledgements

We would like to thank the Hospital Alemão Oswaldo Cruz for the support through the PROADI-SUS program.

Abstract

In this project, a mHealth tool for smart-phones has been developed using Design Science methodology, where the goal has been to promote an active lifestyle. This was undertaken by implementing social and physical activity stimulating features within the application MoveFit. Users can opt to utilize just a feature or two or engage in social activities of different intensity. Regular and expert users have evaluated the application in order to meet usability requirements. In addition a field expert and a focus group have contributed towards the application’s potential to increase physical activity.

There was enough data collected by the app to document its good effect; it was possible to demonstrate that the app was capable of promoting physical activity. User testing has also shown the appreciation of the various features such as social networking, activity monitoring, and route/activity creation.

Keywords:
Sedentary Lifestyle; Application; Social Networking

Introduction

According to World Health Organization the worldwide prevalence of obesity nearly doubled between 1980 and 2008, emphasizing its level of significance [1]. Obesity is often resulting from a sedentary lifestyle, which is also often connected to depression, cardiovascular diseases, diabetes, and some types of cancer. Sedentary lifestyle seems to have become a quite common problem, some people tend to be less active, which in conjunction with unhealthy eating habits, is resulting in high rates of obesity [1]. Technologies such as the Computer and TV are influencing people to stay inactive for longer periods of time.

The World health organization (WHO) has stated that inactivity is the fourth most leading risk factor for global mortality. What is surprising is the severity of health risks from this sedentary lifestyle. Harvard Medical School finds an accelerated risk of diabetes, high cholesterol and heart disease, primarily due to cardiovascular problems.

It is interesting to note that this applies to the “average” person who now spends more than half their waking day sitting still. The American Journal of Preventative Medicine [2] echoes these findings, also concluding that they cannot simply be dealt with by occasional strenuous exercise like going to the gym once in a while. The rapid technological advances which have led to this problem e.g., computers in the office, can also be re-applied toward designing a non-intrusive solution, that will address this problem. While it is often necessary to sit still for hours on end, there is no need for this time to be uninterrupted. For the rest of our careers, good habits in terms of taking regular breaks will prove invaluable, and ways to emphasize this in the workplace, schools or at home is essential.

mHealth (mobile health) is an emerging field that addresses issues such as sedentary lifestyle by use of mobile technologies. The project presented here has focused on developing a mHealth app that counters sedentary lifestyle, by allowing the users to create routes/activities, social networking and activity monitoring. The application is location based i.e., the users find activities/routes or other users in the nearby area.

MoveFit Application

There were several research questions to be answered prior to and through the development of the application. Some of those are: ‘Is it possible for a mHealth application such as MoveFit to reduce sedentary lifestyle?’ and ‘Can a mHealth application such as MoveFit promote psychological health?’

The design of the app includes features to answer these questions and to address various user groups’ needs. This allows various degrees of engagement and activities tailored to suit the different user groups.

Some of those potential users need to be just initialized into a more active lifestyle while the others would just need to be challenged more to diversify their activities and use social media to meet in person, as well as getting more active and social at the same time. This is one of the major challenges for the social media user in general. Furthermore it is possible for people all ages to do or create activities that are corresponding to their respective activity level. For instance a relatively inactive person can start off with an easy activity, with a shorter distance and from there on progress gradually.

Methods

This project has utilized Design Science and System Development as a multi-methodology. Hevner’s 7 guidelines were used to design the artefact [3]. Several system development methods were used. Prototyping was the suitable model, whereas TDD, XP and Personal Kanban were methods and frameworks applied. Both qualitative and quantitative methods were used for empirical research, resulting in mixed methodology usage.

The application was evaluated by both end users and expert users. These two groups were observed while assessing the system. A focus group was also participating in the system evaluation, from the first prototype to the finished product. Furthermore a field expert was consulted in order to shed light
on the effect this application can have to the mental issues related to sedentary lifestyle. This will be elaborated more in the Results Chapter.

Quantitative Survey

For the quantitative research three different surveys have been used. The surveys have been both structured and semi-structured in the sense that they have predefined response alternatives, as well as comment fields. The first survey is for “normal” users i.e., end users without any required technical background in IT. This survey is based on System Usability Scale (SUS) [4] and it aims to find out how non-experts handle an artifact such as the app developed in this project. The intention with that was to see whether it is easy or hard to use and understand the app. The users were given predefined tasks to perform before answering the survey.

The second survey was aimed at “expert” users i.e., those who have background in IT. They were given the same set of tasks to perform and then answered the survey. Nielsen’s heuristics [5]. As with the first survey, it was structured.

The last survey was more related to the actual users, in terms of what their subjective opinions on the application are and physical activity. This survey was semi-structured as it is possible to write comments in addition to the predefined answers. This survey was given to the focus group. A focus group is a form of group interview where there are several participants in addition to the moderator.

Qualitative Observation

Observation is another qualitative method that has been used in this project during the evaluation and data collection process. In this case controlled environment observation has been used which refers to the participants who are performing specific tasks in a controlled environment [9]. While the participants were performing the given tasks, the evaluation leader was observing them to see what kind of problems that might occur. This is useful as the evaluators can communicate their problems as they happen and the evaluation leader can take notes and analyze them later.

Results

This chapter will give an overview of the system evaluation results, as well as the findings from the data collected by the app.

End User Evaluation Results

In the figure below (Table 1) we can see the results from the end user evaluation. There were 10 evaluators. They were given 10 predefined tasks to execute before they were given a survey. They were given the well-known System Usability Scale (SUS) survey.

The average score from the evaluation was 74.7 / 100 which is considered a good score. One of the evaluators did not complete the survey and was therefore excluded from the final score.

Expert User Evaluation Results

As with the end user evaluation, there were 10 users performing the 10 same tasks. They were given a survey after completion. The evaluators were given Nielsen’s Heuristics to assess the system. The figure below is showing an answer of

![Match between system and the real world](image-url)

**Figure 1 – Nielsen’s Heuristic Sample.**
one of the heuristics with corresponding statistics. As we can see, this particular aspect scored 74.4 / 100.

“Documentation and Help” heuristic for instance, only scored 4.6 and ought to be improved in future development iterations. The total score from the evaluation was 6.1 / 10. Indicating that there is some room for improvement in terms of user-interface and usability of the app.

**Focus Group Evaluation**

After publishing the application the focus group was asked to give their assessment. They were given a semi-structured survey. One of the questions given was “Which features of the application do you like the most?”. We can see from the figure below that the route/activity creation and the social features were the most popular ones.

![Figure 2– Popular Features](image)

**Field Expert Elicitation**

A psychiatrist from Helse Bergen was interviewed in regards to the app's potential to effect mental issues related to sedentary lifestyle.

**Interview Summary**

The interviewee shed light on several important questions. For instance the fact that sedentary lifestyle indeed does negatively affect mental health and in those cases physical activity is recommended to counter sedentary lifestyle. It was also brought forth that the health institution Helse Bergen does not enforce use of mobile technologies as a part of patient treatment, although there are apps that are recommended for that purpose. The interviewee seemed rather unsure whether for instance hospitals ought to use mHealth apps which would depend on the patient and the condition. She would prefer to use dialogue instead. The interviewee was also positive when asked if moveFit could have a good effect on physical and mental health, with the exception of people who are really struggling. After being asked about any improvements, she suggested several interesting features that could be implemented. For instance a patient tracking system, where the therapist could communicate with the patient and follow up the patient's progress.

**Application Data**

Since the app was published on Google Play in late September of 2016, the application has been collecting user data. This data is related to the application core features. The core features of the app are:

- Route/Activity Creation
- Activity Alarm
- Social Networking

The user can create their own routes or activities and earn points depending on the route type and length. These points are used to compete with other people in the area. Figure 4 below is showing an example of a route create by a user.

![Figure 3– Sample Route](image)

The activity points are visible in a scoreboard. There is one scoreboard for the user and one for the routes. Routes are sorted by highest review, while points sort users. Figure 4 is illustrating this.

![Figure 4– Scoreboard Users](image)

**Discussion**

The Design Science approach was utilized in this research as the guiding principle to answer the research question. Following the guidelines by Hevner et al. [10] for doing design science research- was very helpful for securing the holistic structure of the research conduct. The final results of the research, following these guidelines are: a functional application (app) developed and evaluated using well defined methods. These methods regard the feasibility of the app to promote physical activity and to utilize the ways that the social medial functions. There is another social dimension: besides aiming at developing a potential to improve a general well-being and health at a personal level, the society at large could in turn benefit through reducing health costs and improving the health care outcomes. The Design Science framework enables another step and that would be testing the application in a clinically controlled manner such as a clinical trial.

In this project a mobile application has been developed in order to see to which extent it can influence health by encouraging
the users to be more active. The goal is to counter a sedentary lifestyle. The developed app is offering different functionalities that promote activities, which was also evaluated by 25 users. The evaluation was positive and constructive, the focus group reported increased physical activity. Furthermore, potential of the app to improve sedentary lifestyle was appraised by the field expert. The data collected from the application is showing that users have been physical active. They have created/completed routes or activities, established friendships, and responded positively to the activity alarm, indicating that the application has had the intended effect. The amount of active users is relatively low, and therefore a larger test should be conducted over a longer period, with more users, to get a definite answer to which extent physically activity is increased. Figure 5 below shows the activity alarm screen.

![Activity Alarm](image)

**Figure 5—Activity Alarm**

Other research has also shown that mobile health technologies have had a positive effect on physical health. Actual change in health this far is hard to determine as it has not been tested with clinical endpoints, although there is research connecting physical activity to better health in general.

From the экспerts point of view it would be possible to promote psychological health with mHealth applications and more specifically with the application presented here. The main reason behind this is due to the social and activity promoting features contained in the app. Although this is the case in general, it was brought to attention by the expert that people suffering from for instance severe depression, would most likely not use these types of applications in the first place. Furthermore, the expert expressed that the ideal situation would be to use this kind of application in conjunction with conventional therapy, such as talk therapy. Previous research has shown positive results in terms of promoting psychological health with mHealth. Fox [11] has shown that psychological health is positively affected by physical activity and that exercise is used as treatment on e.g., clinical depression.

**Conclusion**

This research addressed a crucial problem in our society, namely sedentary lifestyle and chronic diseases caused by it. The main scientific approach that was used is Design Science methodology. The resulting artifact is a social fitness app. The application appeared to have a positive effect on the users as well as the focus group in terms of promoting physical activity. User testing has also shown the appreciation of the various features such as social networking, and route/activity creation. The system evaluation has reached satisfactory scores in terms of functionality and usability. The field expert that was consulted saw great potential in this type of application and suggested that the app could be targeting user groups with conditions such as depression, obesity, and chronic diseases. Other research is also suggesting that mHealth apps do have a good effect in terms of promoting physical activity [12].

There was enough data collected through the testing period to document that the various features are working according to the user requirements. Due to the social nature of the features it could be expected that more ideas would be generated by new users and thus leading to new development iterations.

Long term effect of the app has yet to be probed in a different setting. One way would be conducting a proper clinical trial with end points that will look deeper into the efficiency and potentials of helping selected user groups. That will require resources and experts of other fields to work together.

**Acknowledgements**

The authors acknowledge the expert and end user evaluators and the focus group for their contribution to the research presented in this paper. A special thanks goes to the clinical psychologists who provided her insight into the therapeutic aspects of mHealth in treatment.

Abstract

In radiology diagnosis, medical images are most often visualized slice by slice. At the same time, the visualization based on 3D volumetric rendering of the data is considered useful and has increased its field of application. In this work, we present a case-based study with 16 medical specialists to assess the diagnostic effectiveness of a Virtual Reality interface in fracture identification over 3D volumetric reconstructions. We developed a VR volume viewer compatible with both the Oculus Rift and handheld-based head mounted displays (HMDs). We then performed user experiments to validate the approach in a diagnosis environment. In addition, we assessed the subjects' perception of the 3D reconstruction quality, ease of interaction and ergonomics, and also the users opinion on how VR applications can be useful in healthcare. Among other results, we have found a high level of effectiveness of the VR interface in identifying superficial fractures on head CTs.

Keywords:
Diagnostic Imaging; Image Processing, Computer-Assisted; User-Computer Interface

Introduction

In healthcare, Virtual Reality (VR) has been applied mostly on 3D simulations for training or planning surgeries. Virtual simulators have been especially successful in training minimally invasive and robotic procedures [1]. In diagnosis, however, while 3D image acquisition is ubiquitous (e.g. CT and MRI), the outgoing images are still most often visualized slice by slice or printed out for posterior analysis. One reason is that 2D slices show both internal and external structures in one image. Spatial information, however, is lost. While volume visualization is capable of solving this problem, it faces the difficulty that more internally located structures may be occluded by structures near the surface [2]. In some specific cases only (e.g. planning surgeries and complex fractures), a visualization based on 3D volumetric rendering of the data is considered useful and is currently applied. Even in such cases, the volume is exhibited as an interactive projection on conventional 2D screens and manipulated with mouse and keyboard. On the other hand, the recent popularity of 3D TV and theatres motivated the research on stereoscopic displays for spatial tasks in medical applications [3]. Similarly, the widespread of off-the-shelf VR devices, e.g. Oculus Rift, has attracted the interest of healthcare professionals to a broader range of VR medical application.

The advancement of this area requires a research effort to establish which cases really benefit from a VR interface. Besides, a thorough experimentation will be required to quantify gains for the medical workflow, the patients' health and the healthcare system as a whole. One key element of using VR in any application is that it renders a comprehensive and intuitive visual representation of the data even for the non-specialist. This opens the possibility to provide exam data to referring physicians that can be used for detailed surgery planning and communication with the patients during medical appointments. Another advantage of VR is that immersion in a virtual environment provides a theoretically unlimited field of view and volume space for the radiologist to organize both 2D and 3D (eventually 4D) data representations, maximizing the compromise between focus and context, increasing the efficiency of the analysis [4]. This is crucial as the profusion of data to be analyzed by the radiologist grows fast as new acquisition modalities and diagnostic techniques evolve.

In a preliminary study with 10 radiologists, we investigated the importance of 3D volumetric reconstructions in the medical workflow. All participants marked the diagnostic option (100%), but only for specific cases such as to search fractures. Other areas have also been mentioned, including surgery planning (90%), educational presentations/classes (70%), operating room, patient appointments and discussion with colleagues (60%). One of the possible innovations in the workflow is the generation of a 3D printed model of the patient specific-anatomy and pathology [5]. However, it is still expensive and limited in terms of modeling soft tissues and model modification. VR is a more flexible and inexpensive alternative.

Given this context, we report, in this paper, a user study to assess VR usage in the diagnostic procedure of fracture identification. Our premise is that VR technology allows for accurate diagnosis with high efficiency. Moreover, we report an exploratory study on the potential of immersive VR for other 3D image-based medical applications, such as virtual endoscopy, surgery planning and patient appointments. The development is focused on two key elements: the first premise is based on the communication between radiologists and referring physicians (e.g. surgeons, cardiologists and orthopedists). As shown in a related work [6], 80 to 90% of referrers agree that the discussion between these professionals improved their understanding of the radiology report, affected patient management, and enhanced radiologists' role. However, as a consequence of an ever-increasing use of teleradiology, the radiologists began working remotely (outside of the clinics and hospitals). Thus, their contact with physicians and patients has substantially reduced. The second premise is that in most cases...
the physicians have only the report and raw images, which are poorly comprehensive. Such doctors have knowledge of the patient’s clinical case but are dissociated from the imaging result.

Related Work
Ricciardi et al. [7] discussed a medical viewer for 3D environments that can be usable on either desktop, head-mounted display or CAVE. This system allows for inspection of CT and MRI sequences superimposed to the 3D volume made from those images. The software is able to simplify the understanding of complex datasets increasing the visualization realism of anatomical structures by enabling the user’s depth perception of the models. No clinical application or evaluation is reported. Similarly, Hänel et al. [8] explore a combination of 2D and 3D images to provide a better understanding of structural changes in the brain of a person with corticobasal syndrome. This system allows for the display on conventional monitors and immersive environments with stereoscopic visualization to improve depth perception. The results show a significant improvement in the spatial localization of brain structures affected with this syndrome. In diagnosis, King et al. [9] present an immersive virtual reality environment for radiologist work. The study explores a larger screen area provided by VR in comparison with conventional monitors to optimize the volume of images analyzed simultaneously. An application with multiple 2D- only image views was developed on the Unity platform. It is possible to interact with the application through an HMD and to adjust images windowing with a game controller. The system was used for CT visualization of a patient with a lung nodule and multiple-sclerosis lesion evolution of MRI dataset. Validation experiments for the usage of the system in differential diagnosis and remote collaboration were presented. The Oculus Rift was explored in virtual colonoscopy (VC) procedure [10]. A preprocessed mesh is loaded into a virtual environment developed on Unity. Then, a VR camera is assigned to travel both outside and inside the colon, aided by joystick controls. Two radiologists and a gastroenterologist experienced the application, without clinical purposes. The results showed the potential of this technology to improve diagnosis, but emphasize the need of future deployments to provide maximum performance. Likewise, Mirhosseini et al. [11] studied the benefits of 3D immersion for virtual colonoscopy using a CAVE. The authors highlight the benefits of 3D interaction techniques to improve cancer screening in VC.

In these previous studies, the authors present their efforts to establish new techniques of 3D immersive visualization and interaction in medical context. Nevertheless, the VR technology is not widely used in routine medical procedures, such as diagnostic image analysis. Our approach evaluates the diagnostic effectiveness and quality of 3D volumetric reconstructions made for current VR devices.

Methods
In order to measure the capabilities of VR in the diagnostic procedure of fracture identification, we performed a between-subject task-analysis using two CT-scan datasets. Each subject, wearing a head-mounted display and using a couple of interaction tools (windowing and zoom), tried to find fractures in one of the studies. We monitored four dependent variables: the diagnostic effectiveness, 3D images quality, ease of interaction and cyber sickness. This study was approved by the Institutional Review Board of our institution (nbr. 1.782.728).

System Design
We have developed an engine able to apply multiplanar and volumetric reconstructions in tomographic imaging (CT and MRI scans). The system has been designed using the Unity platform and parallel GPU processing.

The visualization engine runs on either a PC with the Oculus Rift or on a smartphone adapted as an HMD using Google Cardboard or other off-the-shelf or 3D printed mobile HMDs. Both platforms allow rotations, translations and windowing (i.e., to select the density corresponding to bone or soft tissue) in the reconstructed volume. A simple switch action, such as a click on a joystick or a trigger on the HMD, allows navigating through the visualization options. Fig. 1 (right) shows users interacting with a joystick to control windowing and zoom. Viewpoint is controlled with natural head rotations to look for a target position in the 3D volume.

![Figure 1](https://example.com/figure1.png)

**Figure 1** - Integration of the VR interface with PACS. A 3D VR button is shown at the top of the left image. It triggers the 3D VR engine. On the right, we show the users interacting with a 3D dataset through our VR interface.

![Figure 2](https://example.com/figure2.png)

**Figure 2** - A typical timeline of user actions with the interface. T0 shows a centered initial position and windowing in tissue range. At T1, the windowing tool is activated through a click and the parameters are set to highlight bones. T2 shows the volume rotated due to a head movement. At T3, the zoom tool is activated to provide details on a specific region. Fig. 2 shows an example sequence of actions applied with our interface. T0 is the initial state in which the 3D volume is displayed in the center of the screen with standard windowing and viewpoint. At T1 a joystick button is pressed to activate the windowing adjustment tool, displaying the two bars with window width and center values. They are changed moving the analog stick in four directions. The result of this change is observed in the second image, highlighting the density range of bone rather than soft tissue. The picture in T2 represents the user’s head movement, which causes a rotation around the object. This natural head movement can be performed until a position of interest is reached. Finally, on time T3, a switch action is triggered again, this time enabling the zoom tool. This tool changes the distance to the object using the analog button movement, to focus on a bone fracture for instance.

Study Selection and Analysis
We selected two specific exams for our analysis. The exams have been searched in the partner clinic's database with the strings: comminuted fractures, bone fracture and polytrauma. Head CT studies appeared as a convenient choice as they are common in routine examination of trauma situations. Moreover, they are suitable for analysis by any radiologist, regardless of specialty. The two head CT studies with the highest number of fractures were selected and anonymized. The first one (a) with 191 slices, thickness 1 mm and bone filter applied in the acquisition. The second dataset (b) has 231 slices and the same thickness of the first.

We conducted a preliminary interpretation to identify existing fractures in each data-set. Three neuroradiologists with 5 to 10 years of experience performed this analysis. Clinical findings were obtained by viewing images in the conventional way (i.e. desktop computer and 2D monitor), using slices in the axial, sagittal and coronal planes, in conjunction with the 3D volume. Seven fractures have been identified in the dataset a, and six in dataset b by the committee of 3 experts. Doctors emphasized that some of these fractures are internal and small, hardly interpreted only viewing the 3D volume as they may be occluded by structures near the surface. After the studies interpretation, we prepared two lists with the clinical findings of each dataset. In each list, we included two additional fractures that do not exist to provide false alternatives. In some of them, we simply reversed the laterality of fracture. In other cases, false alternatives pointed to non-existing fractures in locations near existing ones.

Experimental Setup
Fifteen radiologists and one medical physicist participated voluntarily in the study (thirteen males and three females). Their times of experience ranged from 1 to 5 years (56.3%), 5 to 10 (25%) and over 10 years (18.8%). The subjects have subspecialties in radiology. The 33.3% are members of the neuroradiology team, followed by 26.7% of specialists in abdominal radiology, 26.7% in musculoskeletal, 6.7% in thoracic and 6.7% in other subspecialties. This study was the first experience with virtual reality for 81.3% of participants. The main user task in our experiment is to find fractures in a reconstructed 3D volume in an immersive environment by applying transformations (such as zoom and rotation) and windowing adjustment. No additional clinical information or viewing in 2D planes were available. Furthermore, no cutting planes were allowed in this version of the interface to prevent users to simulate slice-by-slice visualizations. Initially, each participant signed a legal term of consent informing about the compliance with ethical precepts and the details of the experimental protocol. Before starting the experiment, all the subjects also filled out a characterization questionnaire. The following step was an interface learning session in which a video demonstrating the use of the application and methods of interaction with the HMD and joystick was presented. No preliminary training was allowed. For this experiment, we chose to use the Oculus Rift DK2 attached to a desktop computer. This choice has been motivated by the wider availability of the device, which can be useful for comparison by other researchers, and due to the device specifications, e.g. higher resolution and performance when compared with Google Cardboard interface. The resolution displayed to each eye by the Oculus Rift DK2 is 960 x 1080 pixels, refresh rate is 75Hz, and field of view is 100°.

After the learning session, the user performed the task of finding fractures in one dataset for 2 to 5 minutes according to their preference. Eight users viewed dataset a and the other 8 analyzed dataset b. Finally, subjects filled out a post-questionnaire with questions about the list of possible fractures found, ease of interaction and comfort during the task. For the comfort analysis, we adapted the Simulator Sickness Questionnaire (SSQ) [12], using the questions most related to our case. The list of possible fractures has been defined in the preliminary interpretation with true and false alternatives. Participants can select as many alternatives as they wish.

Results
The results are presented here. Authors may choose a combination of text, tables, figures, and graphs to convey the results of their work to the reader. There are no set limitations on the number of tables, figures, and graphs that may be used in papers, posters, and proposals. Large figures and tables may span two columns. Please number tables and figures and reference them appropriately in the text.

We report results on the users' performance in identifying fractures, the subjective quality of the reconstructions and subjective comfort/discomfort.

Diagnostic effectiveness
Figs. 3 and 4 show the number of responses on each of the possible observations on the datasets a and b respectively. The options with marker * represent the false alternatives and the maximum number of answers by alternative is eight.

Fig. 3 shows the answers on the second exam (b) with six correct and two false choices. All radiologists found the depressed right anterior maxillary sinus wall (100% hit). Then, the right zygomatic arch and depressed right anterior frontal sinus wall received 7 votes each (87.5% hit). The posterior maxillary sinus wall, which is an internal structure, scored only two votes (25%) and other 2 correct fractures in internal structures have no vote. This was expected, as the ethmoidal cells, posterior frontal sinus wall and posterior maxillary sinus wall are internal head structures, hardly seen without making
cuts in the 3D volume or viewing on 2D slices. In the preliminary interpretation, the radiologists explicitly pointed to this possibility, and these results demonstrate that.

<table>

</tbody>
</table>

Figure 5 - The bars represent the percentage of user selections for each fracture type. The * indicates that the respective bar represents a non-existent fracture.

Similarly, to the first exam, the dataset b scored only one vote in one of the false alternatives (left nasal bone), and none in the other. The exam presents facial polytrauma affecting nearby structures. This seems to have induced a participant to precipitate (rather than perception). The lateral left orbit wall had no marking, as expected.

As we hypothesized, these results showed a high accuracy rate identifying superficial fractures in both studies. Most radiologists, regardless of experience and specialty, found the outer skull fractures, for instance, in the zygomatic arch, anterior maxillary sinus wall and lateral orbit wall. Thus, we emphasize the high diagnostic effectiveness obtained with the VR interface, even though it was the first contact of the subjects with an immersive VR system. Results have also shown a limitation for identification of the internal fractures, which was expected as they are occluded by surface elements.

Usability and Quality
We also analyzed two variables related to our interface: ease of interaction and quality of 3D reconstructions. The subjects graded the easiness of interacting using our interface compared to other interfaces for 3D data they are familiar with, e.g. their conventional workstations where mouse and keyboard are used to apply transformations in volumetric images. They also graded the quality of the 3D reconstructions in comparison with the conventional volumetric images, which most often are preprocessed on the acquisition equipment and then sent as 2D images for the radiologists. The responses were collected in a five points Likert Scale questionnaire, from 1 (very low) to 5 (very high).

Fig. 5 shows the percentage of selections in each level for quality and ease of use (usability) for both datasets. Concerning usability, the two studies had no negative selections. The general average was 4.0625 points (avg = 5, min = 2, stdev = 1.44). This assessment reflects the simplicity of our interface to focus on a region (zoom + head rotations) and to set parameters of interest (window).

Concerning the quality of the reconstructed image volume, we rely on the subjective analysis of radiologists and medical physicists, who are very demanding in terms of image attributes. In both studies their answers present a general average of 2.85 (max = 5, min = 2, stdev = 1.1474). The visualization of dataset a (avg = 3.125) has been perceived as of better quality than the dataset b (avg = 2.65), even with a smaller number of slices. This probably occurred due to the bone filter used in image acquisition, highlighting the surface structures and consequently generating a sharper image.

Notice that the image quality is impaired by the relatively low resolution of the Oculus Rift DK2. Besides, the algorithms have been optimized to run on mobile devices while most 3D images currently available to radiologists are processed on dedicated workstations. Despite these limitations, they were able to diagnose the surface fractures of the volume, as previously shown.

Exploratory Analysis and Discomforts
Another contribution of our research is the user’s opinion about where VR applications can be useful in medicine. According to 75% of radiologists, a VR interface such as ours has benefits in virtual endoscopies, like colonoscopy, where the conventional procedure is the use of mouse and keyboard to navigate in a 3D volume displayed on a 2D monitor.

The 68.8% of the participants think this interface would be useful for communication with referring physicians. The doctors explained that medical assistants have difficulty understanding the 2D slices. They are unable to make an appropriate mental spatial reconstruction. Recent work [6] has shown that promoting communication between the radiologist and the referring physician improved the understanding of the images and the exams report, consequently affecting patient healthcare. Our results highlight the potential of VR to analyze 3D images with intuitive visual representations that instigate discussion among the medical staff. This is particularly important in planning surgery and analyzing complex fractures, as highlighted by 75% of subjects.

We then explored further, asking the participants what tools they would like to see integrated into the interface to help them in diagnosis. Most of them (62.5%) indicated that oblique cuts in the volume (in arbitrary planes) would be useful. This is reported to be crucial to visualize internal structures. The use of transparency in the mapping of windowing parameters to the volume rendering helps seeing internal structures. However, it is known that humans do not deal well with several transparent layers [13]. Besides, 10 physicians (62.5%) would like to be able to navigate in 2D planes with reference lines/planes displayed in the volume. VR provides a 360° wide visualization space that enables volume and planar views to be placed side by side.

Finally, eventual discomforts with the interface were measured with an adapted Simulator Sickness Questionnaire. All participants performed the task standing upright and without prescription glasses. Fig. 6 shows the distribution of the discomforts reported by the subjects. Overall, a very low level of discomfort was reported. Blurred vision was the main issue, affecting nearly 25% of the users. Similarly, 3 participants reported eyestrain (2 moderate and 1 severe). These are linked to 5 users that reported some degree of myopia. In a day-by-day workflow with a VR interface, they should be allowed to wear their prescription glasses or adjust the HMD optics individually.
General discomfort  Vertigo  Dizziness  Blurred vision  Nausea  Eye strain  Headache  Fatigue

0%  20%  40%  60%  80%  100%

Severe  Moderate  Slight  None

Figure 6 - Each bar shows the intensity of each evaluated discomfort during the execution of the fracture identification tasks. The overall discomfort is surprisingly low.

Conclusion

In this paper, we presented a user study with medical specialists to assess diagnostic effectiveness of VR usage in fracture identification. We performed experiments to validate the proposed approaches with sixteen expert professionals in image diagnostic procedures. Subjects were challenged to identify fractures in head CT exams in a virtual environment.

The results have shown high effectiveness in identifying superficial fractures for two different volume exams. However, we found that viewing only the volume surface is not enough for the complete diagnosis, as deeply located internal structures are hard to visualize on the reconstructed volume. These results support our premise of VR being suitable to provide a more intuitive interface for the whole chain of the medical care. One remarkable observation is that it may encourage communication between referring physicians and radiologists as it increases the exam comprehension by the non-specialist. Increased communication is often correlated with better decision-making [6].

Future work should focus on the assessment of long term use of VR goggles for image-based diagnosis.

Preferred Features of E-Mental Health Programs for Prevention of Major Depression in Male Workers: Results from a Canadian National Survey

JianLi Wang and Kendall Ho

* Institute of Mental Health Research, University of Ottawa, Ottawa, Ontario, Canada,
* Digital Emergency Medicine, University of British Columbia, Vancouver, British Columbia, Canada

Abstract

The purpose of this study was to estimate and compare the proportions of preferred design features and likely use of e-mental health programs and understand potential barriers to the use of e-mental health programs in working men who were at high risk of a major depressive episode. A cross-sectional survey in 10 provinces in Canada was conducted between March and December 2015 (n = 511). Of the 17 different features assessed, the top three features that were most likely to be used by high-risk men were: “information about improving sleep hygiene” (61.3%), “practice and exercise to help reduce symptoms of stress and depression” (59.5%) and “having access to quality information and resources about work stress issues” (57.8%). E-mental health programs may be a promising strategy for prevention of depression in working men. Development of e-mental health programs should consider men’s preferences and perceived barriers to enhance the acceptability of this approach.

Keywords:
Mental Health Services; Program Development; Depressive Disorder, Major

Introduction

Major depression is a prevalent mental disorder. In Canada, the annual prevalence of major depressive disorder was 3.9% based on the DSM-IV criteria [1]; in the United States, the 12-month prevalence was 6.6% [2]. Major depression is also disabling and significantly affects workers’ health and productivity. Depression alone accounts for 2.5% of the global burden of disease and is among the largest single causes of disability worldwide (8.2% of all years lived with disability globally) [3]. US workers with depression cost an estimated US $44.01 billion per year in lost productivity [4]. Epidemiological studies have consistently found that women are more likely to have major depression than men. However, men are not immune to depression. Canadian national data showed that annually, 2.8% of adult men have a major depressive disorder [1]. One of the severe consequences of having a major depressive episode (MDE) is suicide. Canadian national data showed that 75%-80% of all suicides were male [5, 6].

Given the considerable impact on health, productivity and lives, there is a pressing need for innovation in the prevention of major depression in male workers. However, this is a challenging endeavor. In the workplace, risk factors for having MDE differ for men and women [7-9]. For instance, job strain, family to work conflict and job insecurity appear to be more prominent MDE risk factors in men than in women [7, 8]. Compounding men’s risk, men are less likely than women to seek help and to disclose depressive symptoms and often delay seeking help until symptoms become severe. Men tend to be socialized to be emotionally stoic and exemplify traditional masculine characteristics such as independence, self-reliance, and dominance [10]. Men are concerned over the perceived negative judgments from family, friends, and co-workers if they access treatment for depression. These gender-specific experiences together with a limited knowledge base about effective interventions call for innovative solutions tailored for men. One of the burgeoning solutions that have attracted considerable interests is e-mental health.

E-mental health is “the use of information and communication technologies to support and improve mental health, including the use of online resources, social media and smartphone applications” [11]. E-mental health self-help services enable users to learn more about their mental health conditions and empower users to strengthen their self-management and improve their health. The majority of e-mental health treatment programs were developed based on the models of cognitive behavioral therapy (CBT) or interpersonal therapy (IPT) that demonstrate evidence of effectiveness for depression and anxiety [12]. A review by Christensen and Petrie showed that by 2013 there had been 62 web-based mental health interventions and 11 mobile applications [13]. Lal and Adair found 91 peer-reviewed publications on the application of e-mental health interventions between 2000 and 2010. Thus far, randomized controlled trials of e-mental health interventions on depression have been conducted with samples of individuals who have clinical depression or are above a threshold of a depression rating scale [14]. Consistent with public health mandates to reduce the burden of depression, it is important that e-mental health not only addresses needs of those with depression or who are above a depression rating threshold, but also advances capacity for secondary prevention [15], i.e., identifying high-risk individuals and intervening to prevent early symptoms from progressing into an MDE. Additionally, existing e-mental health programs have not been designed and evaluated using a gender lens. Given the gender norms, the extent to which e-mental health programs are accepted by men is unknown. The effectiveness of the program and its acceptability to users constitute the foundation for scalable and sustainable program implementation. Therefore, as part of the BroMatters study (www.bromatters.ca), we conducted a cross-sectional survey in working men, some of whom were at high risk of MDE, to understand their preference of design features of e-mental health programs.
The objectives of this analysis were, amongst male workers who were at variable risk levels of MDE, to 1) estimate and compare the proportions of Internet use for medical information, preferred design features and likely use of e-mental health programs, 2) examine factors associated with the likely use of e-mental health programs, and 3) understand potential barriers to the use of e-mental health programs in working men who were at high risk of MDE.

Methods

A cross-sectional survey was conducted between March and December 2015. The target population of the survey included Canadian working men who: 1) were aged 18+, 2) did not have an MDE in the past 12 months, 3) were at high risk of MDE at the time of interview (a low-risk sample was also obtained for comparison), 4) were working at the time of the survey, and 5) have no language barriers to either English or French. Because of the vast geographic area of Canada, participants were recruited using random digit dialing method by Bureau of Professional Interviewers (BIP) located in Montreal Canada. The BIP has the access to household telephone numbers across the country and to a validated cell phone number database, and its interviewers can conduct interviews in both English and French. The study was approved by the Conjoint Health Research Ethics Review Board of University of Calgary.

Once a household was reached, the household contact was asked to retrieve, or provide contact information (e.g. a first name) of the household residents who are men and are currently working. If there was more than one potentially eligible individual in the same household, one was randomly selected. Once the prospective participant was fully informed about the objectives and procedures of the study, oral consent was obtained to proceed with the interview. Participants were first administered a risk calculator for MDE to estimate their probability of having MDE in the future. The definition of high-risk is described below. The number of high risk participants in each age group was proportional to the age distribution of Canadian male working population in 2014, provided by Statistics Canada.

From March to December 2015, 49,500 calls were made. A majority of the calls (47,648, 96.2%) were not valid (not in service, fax/modem, answering machine, language barriers, ineligibility, duplications, refusal before eligibility was assessed). Among 1852 eligible participants, 596 (32.1%) refused to participate after verifying eligibility; 842 provided completed data (45.4%); the remaining included incomplete interviews and scheduled call-backs not in the study period (22.5%). After removing one duplication, 841 participants were included in the analysis, including 511 men who were at high risk of having major depression and 330 who were at low risk of having major depression.

Measurements

A multivariable risk prediction algorithm for major depression in men was administered to estimate the risk (probability) of having MDE in the next 4 years for each participant [16]. This risk prediction model was designed to be used in individuals who do not have an MDE. Based on participant’s exposure to a key set of risk factors (predictors) in the model, the algorithm can generate the absolute risk/probability of having MDE in the next 4 years, analogous to the Framingham risk prediction algorithm for coronary heart disease [17, 18]. The risk prediction algorithm for MDE in men was developed and validated using data from 4737 Canadian men who were aged 18+ years and who did not have MDE in the past 12 months [16]. The risk prediction algorithm contains 15 predictors including age, personal and family history of MDE, childhood trauma, ongoing stress and life events, and anti-depressant or sleeping pill use in the past month. The predictive power of the risk prediction algorithm was measured by C statistics (C > 0.7953) [16] which is equivalent with area under the curve when the outcome is binary. The model had excellent calibration with data as indicated by the Hosmer-Lemeshow test and visual comparison between the predicted and observed risks by decile risk groups [16]. In our study, 6.51% were defined as high risk for men, which represents the top two decile risk groups in the Canadian male population. The predicted risk that was lower than 6.51% was defined as low risk.

Internet use was assessed using questions from the 2012 Canadian Internet Use Survey conducted by Statistics Canada. Preferred design features of e-mental health program questions were developed by the BroMatters team members. Participants were asked “We want to hear your opinion about e-mental health programs for dealing with work and stress issues. E-health is defined as ….. For the following features, please indicate how likely it is that you would use them.” Seventeen questions about design features were asked. For each question, participants answered on a 5-point Likert scale ranging from: very likely to very unlikely. Open-ended questions were asked about any other features they may want in an e-mental health program, whether the participant and his male co-workers may use an e-mental health program to deal with work stress, and what make it difficult to use an e-mental health program.

Ineligible participants, administering the questions and instruments took an average of 22 minutes to complete. Participants who completed the survey received a CAN $20 gift card as a token of appreciation.

Statistical analysis

The background characteristics and proportions of likely use of design features were estimated and compared in men who were at high or low-risk levels of having MDE, using Chi square test. In men who were at high-risk of having MDE, the percentages were also estimated and compared by age groups and by language used in the interview (English vs. French), using Chi-square test. All analyses were conducted using the statistical program STATA 14.0 [16]. Tests were considered statistically significant when \( p < 0.05 \). With this level of probability and a sample size of 841, the study had a level of statistical power of 0.89 to detect a small effect size (Cohen’s \( \delta \)) of 0.20.

Results

A majority of the participants reported use of Internet for personal reasons in the past 12 months, with the proportion (95.7%) in the high risk men slightly higher than that in the low risk men (92.4%). The two groups did not differ in Internet use for searching medical information and in perceived usefulness of the Internet information in making decisions about health. However, high risk men (83.4%) were more likely to have reported that it was important to access health resources on the Internet than low risk men (75.0%).

Participants rated their level of interest in possible use of 17 different features that can be incorporated into the design of e-
mental health programs. We ranked the preferred design features of e-mental health program in descending order. The top three features that were identified by high-risk men as things they would likely to use were: “information about improving sleep hygiene”, “practice and exercise to help reduce symptoms of stress and depression” and “having access to quality information and resources about work stress issues”. The proportions of individuals endorsing the selected design features in the high-risk group were significantly higher than those in the low-risk group, except for the feature of “information about improving sleep hygiene”.

We estimated and compared the proportions of preferred design features by age groups and languages used in the interview in men who were at high risk of MDE. The data showed that, compared to older participants (aged 65+ years old), younger participants preferred access to a program through smartphone or mobile applications and that the information be delivered in game format. Middle aged men (aged 30 to 64 years old) had a preference for receiving printed materials. The preferences for other design features did not vary by age.

English-speaking participants were more likely to use “practice & exercise to reduce stress”, “access a program via smartphone or an app.”, and “being able to ask questions and receive answers from mental health professionals” than French-speaking men; French-speaking men were more likely to use “being able to chart and track your mood” than English-speaking participants.

A majority of participants considered our survey questions about preferred design features to be comprehensive and did not have other features to add. For the open-ended questions, some participants suggested that, in addition to the design features encompassed in the survey, other valuable features of e-mental health programs may include: easy to use (e.g., “online information in a format that's simple to use.”), confidentiality (e.g., “Privacy, somehow to ensure privacy”), credibility (e.g., “having access to, to reliable information that's important to me”) and direct link to a professional (e.g., “like some kind of call in line. Like a hotline ……where you could access a live expert….. something personal”). (Note: italics denote direct quotes.)

Among the participants, 69.0% reported “yes” or “maybe” to potentially using an e-mental health program to deal with work stress. The percentage was higher in the high-risk group (72.6%), those in the levels of higher education and personal income, younger age groups, and those working in mid and large companies, compared with their counterparts. No differences were found by language, marital status and employment status (employee vs. self-employed). High MDE risk participants who reported that they would not use an e-mental health program for dealing with stress were asked: “what would make it difficult to use an e-health program?” The reported barriers included perceived stigma associated with accessing e-mental health support (e.g., “…social stigma, comfort of access”, “…workplace ignorance and what do they call that where you stereotype …”), lack of personal interaction inherent to e-mental health (e.g., “lack of personal face to face”, “… don’t see the value of it if you could talk to your family doctor…”), lack of time (e.g., “…if it was time consuming…”), and lack of knowledge (e.g., “Well the fact that I don’t know what an e-health program is, makes it difficult. I’m not sure that (laughs)”). (Note: italics denote direct quotes).

Discussion

This study is descriptive in nature as the results were used for guiding the development of e-mental health program. One key finding of this study was that 62.7% participants who were at high risk of having MDE had used the Internet for health information in the 12 months prior to the survey. This percent is slightly higher than a similar estimate from the 2012 Canadian Internet Use survey, in which 60.8% men reported use of Internet for medical or health related information [20]. Furthermore, over 75% of high MDE risk men in our sample considered health information on the Internet to be useful in helping them make health decisions and over 72% would use an e-mental health program to deal with work-related stress. Given that men often delay help-seeking for mental health problems because of perceived stigma and gender norms, our results suggest that the privacy inherent to e-mental health programs make e-mental health programs a promising tool for improving men’s mental health.

Acceptability of a tool is vital to the evaluation of its effectiveness and implementation. Therefore, to develop e-mental health programs for men, it is critical to understand their preferred design features. It is interesting to observe, in our survey, that “information about improving sleep hygiene” was the top design feature preferred by men, irrespective of their risk status. Individuals who are at high risk of MDE may be occupied by unhelpful thinking and look for strategies to solve the issues they encounter. Thus, it is not surprising that the second top feature they endorsed was “practice and exercise to help reduce symptoms of stress and depression” which is consistent with the principles of CBT, e.g., changing unhelpful thinking and behaviors, and problem-solving focused. We anticipated that CBT practices and educational information (“having access to quality information and resources about work stress issues”) would be needed by the participants and this was demonstrated in this study. This also is consistent with the fact that most of the existing e-mental health programs (such as MoodGYM [21]) were developed based on the CBT approach [22]. We found that men who were at high risk of having MDE were more likely to have endorsed the design features than men who were at low risk. No age differences were found in preferred design features. English- speaking participants were more likely to use CBT techniques and an app and French-speaking participants were more likely to use mood monitoring tools. These results indicate that e-mental health programs incorporating these preferred features are likely to be used by men who are at high risk of MDE across age and English/French speaking categories.

Comparison with Prior Work

An understanding of barriers to the use of e-mental health programs is also important for the development, evaluation and implementation of the programs. Some features preferred by the participants reflect the concerns they have about e-mental health programs and potential barriers to the use. Based on the quantitative and qualitative data, confidentiality and privacy protection are the prominent concerns for high-risk participants. They were concerned about the consequences if others know that they use the program to deal with stress related issues (e.g., perceived stigma). Other barriers include the extent to which the program is easy to use and navigate, credible (e.g., information is provided by health professionals), relevant to one’s personal situation, and interactive (e.g., being able to communicate with a
professional). Additionally, lack of time and knowledge about e-health are potential barriers reported by the participants. Schneider and colleagues investigated users’ views of an online CBT program (MoodGYM) in a randomized controlled trial [23]. Wetterlin et al.’s cross-sectional study examined youth expectations for mental health websites [24]. Both studies reported preferences and perceived barriers that are consistent with the results of our survey.

Our study has several limitations. First, the survey data relied on self-report. Therefore, reporting and recall biases are possible. Second, our target population is Canadian working men who were aged 18 and older. Compared to men in the Canadian workforce in 2014, our sample was slightly older. The proportion of our participants aged 18 to 29 was 12.1%, while it was 20.2% in the Canadian workforce. Therefore, the proportions of some design features by age groups could have been over or underestimated due to potential selection bias. Given the increasing use of cell phones in young adults, future studies may investigate strategies for recruiting young adults through cell phones. Finally, our survey collected self-reported qualitative information about barriers to the use of e-mental health programs. The qualitative information should be considered preliminary. More studies are needed to provide definitive answers.

Conclusions

There is a pressing need for developing innovative strategies for prevention of depression in men. This is a challenging endeavor because of the gender norms and social stigma against depression and help-seeking among men. E-mental health holds potential as it can be confidential, easily accessible and economic if it is appropriately designed. However, the design of e-mental health solutions should consider the sex and age differences in terms of preferred features. More studies are needed to examine preferred design features and the barriers to use in different populations so that e-mental health strategies that meet the needs of different age groups and personal background can be developed.

Abstract

This paper is to document the development process of a smartphone app to track patient-reported outcomes (PROs) of children with chronic diseases, and to share the usability study results. A multidisciplinary research team including health services researchers, pediatric nurses, and software engineers worked synergistically in development. Group discussions and several rounds of feedback and modification were conducted. Ten pediatric patients, five parents, and two nurses participated in usability study. Qualitative content analyses were employed in development and usability evaluation. The app collects demographic information and PROs. The web-based administration portal helps to manage demographic information, questionnaires, administrators, and survey-conducting organizations. All participants felt this app was easy to use and the interfaces were friendly to children. Nurses thought administration portal interfaces were simple and data was convenient to download for further analysis. The app and administration portal have potential to promote PROs in assessing quality of life and symptoms in pediatric patients.

Patients, Mobile applications, Software design.

Introduction

The Patient-Reported Outcomes Measurement Information System (PROMIS) Pediatric Cooperative Group has developed pediatric self-report item banks for youth ages 8-17 years across five generic health domains (physical functioning, pain, fatigue, emotional health, and social health) [1, 2]. Our research team has been authorized to translate the PROMIS Pediatric and PROMIS parent proxy report short forms into Simplified Chinese. Pediatric PROMIS contains instruments for 8- to 17-year-olds [1, 2]. PROMIS Parent Proxy Report Scales for Children were developed for parents of children ages 5-17 years who were too young, too cognitively impaired, or too ill to complete a PRO instrument [3-5]. Computer-assisted tools have been developed in recent years to collect PROs. However, computer-based tools are often only used in hospitals or clinics, which makes it hard to collect PROs when patients are at home in the break before the next treatment. Smartphone applications (apps) have the potential to collect PRO data with high efficiency and effectiveness. Our research team developed a smartphone app to track PROs of children with chronic diseases. This paper aims to document the app development process and share the usability study results.

Methods

This study was conducted in Shanghai, China. This research received ethical review approval from the Second Military Medical University. The PROMIS central administration has authorized us to translate the PROMIS Pediatric and PROMIS parent proxy report short forms from English to Chinese, following the standard Functional Assessment of Chronic Illness Therapy Translation Methodology. All the translation steps and the final Chinese versions of the pediatric PROMIS short forms (C-Ped-PROMIS) have been approved by the PROMIS Statistical Center. The C-Ped-PROMIS items were semantically and conceptually equivalent to the original [6]. A total of 232 children and adolescents with cancer were interviewed with the C-Ped-PROMIS using traditional paper questionnaires. The strict and standard scale metrological test showed the C-Ped-PROMIS measures had good reliabilities and validities. Comparably, reliable and valid instrument systems can be applied in the measurement of symptoms and quality of life of children and adolescents with cancer in China, and then improve pediatric cancer care [7]. We use the validated C-Ped-PROMIS short form questionnaires in our app.

A multidisciplinary research team including health services researchers, pediatric nurses, and software engineers worked synergistically to design and develop the PROs module and administration portal. Figure 1 shows the workflow of the development process.

Group discussion: researchers, nurses and software engineers

Based on the literature review and previous experience of developing an app with a “self-assessment questionnaires” module [8-9], we conducted the first round of focus group discussion with four researchers, two nurses, and two software engineers. The discussion was conducted in a conference room at a medical university in Shanghai and lasted between 120 and 150min. All of these researchers have been involved in translating and testing C-Ped-PROMIS short forms with an educational level of a master degree or above. The nurses had more than ten years of working experience with pediatric patients and have a good understanding of C-Ped-PROMIS. The software engineers were experienced in developing medical-related software or apps.

Discussions were recorded and continued until the same themes and issues emerged from the interviewees. Discussions were transcribed verbatim within two days. Based on the functions described by the researchers, software engineers developed the
beta version of the app and web-based administration portal with basic structure, functions, and interface.

Figure 1 - The workflow of the development process

Feedback and modification: researchers and software engineers

Four researchers tested the beta version of the app individually, and then a group discussion was held to brainstorm about the disadvantages and improvement of the app. Software engineers modified the app according to the feedback. The second version of the app was developed and sent to the researchers. Another round of testing, feedback, and modification was conducted until there were no more items needed to be improved. After software engineers finished developing the web-based administration portal, researchers tested and provided feedback to the engineers for further improvement, following the same procedures as with the app’s modification.

Usability study: pediatric patients, parents and nurses

Pediatric patients and parents were recruited in the Children's Hospital of Soochow University and Shanghai Children’s Medical Center during August 2015. The research team introduced the app and the usability study project. No study procedures were performed until study participants signed the informed consent. The eligible pediatric patients were aged 8-17 years old with chronic diseases. The eligible parents had a child aged 5-7 years old with a chronic disease. The pediatric patients and parents were able to communicate fluently in Mandarin Chinese and had at least one Android smartphone in their family.

We first helped the pediatric patient or his/her parents and the eligible parents to install the most updated version of the app on their smartphones. The participants were asked to register and log in to fill in their basic demographic information in the app first. Then, they entered the questionnaire system to enter answers. The nurses and researchers tested the administration portal to see whether it received the accurate data users entered, and whether it was convenient to export the data for further analysis.

After the usability test, semi-structured interviews were conducted with all research participants. They expressed their positive and negative experiences related to both the app and administration portal.

Data Analysis

Descriptive statistics were used to characterize the study participants. Two researchers transcribed the recorded qualitative data and analyzed the transcripts independently. A qualitative content analysis aimed at finding manifest, and latent meaning of data was applied to analyze the information. A stepwise approach was adopted for the content analysis. Firstly, the transcribed data was read several times by the researcher to find the theme of the whole. Secondly, the segmentation of information was done to organize the segments and sub-segments of information. Thirdly, the significant information related to research questions was extracted. Finally, data was coded and grouped into categories and abstracted into subthemes and a main theme.

Results

Basic function of the app

Six rounds of feedback and modification of the app were conducted before the final version of the app was developed. The app mainly has two modules: the demographic information module and the questionnaire module. Figure 2 (2a-2b) shows the welcome page of this app. Users need to register and log into the app. They need to fill in the demographic information and upload it as required, so they can enter the questionnaire module.

Pediatric Patient-Reported Outcomes Measurement Information System (Pediatric PROMIS)

Pediatric patients and parents were recruited in the Children's Hospital of Soochow University and Shanghai Children’s Medical Center during August 2015. The research team introduced the app and the usability study project. No study procedures were performed until study participants signed the informed consent. The eligible pediatric patients were aged 8-17 years old with chronic diseases. The eligible parents had a child aged 5-7 years old with a chronic disease. The pediatric patients and parents were able to communicate fluently in Mandarin Chinese and had at least one Android smartphone in their family.

We first helped the pediatric patient or his/her parents and the eligible parents to install the most updated version of the app on their smartphones. The participants were asked to register and log in to fill in their basic demographic information in the app first. Then, they entered the questionnaire system to enter answers. The nurses and researchers tested the administration portal to see whether it received the accurate data users entered, and whether it was convenient to export the data for further analysis.

After the usability test, semi-structured interviews were conducted with all research participants. They expressed their positive and negative experiences related to both the app and administration portal.

Data Analysis

Descriptive statistics were used to characterize the study participants. Two researchers transcribed the recorded qualitative data and analyzed the transcripts independently. A qualitative content analysis aimed at finding manifest, and latent meaning of data was applied to analyze the information. A stepwise approach was adopted for the content analysis. Firstly, the transcribed data was read several times by the researcher to find the theme of the whole. Secondly, the segmentation of information was done to organize the segments and sub-segments of information. Thirdly, the significant information related to research questions was extracted. Finally, data was coded and grouped into categories and abstracted into subthemes and a main theme.

Results

Basic function of the app

Six rounds of feedback and modification of the app were conducted before the final version of the app was developed. The app mainly has two modules: the demographic information module and the questionnaire module. Figure 2 (2a-2b) shows the welcome page of this app. Users need to register and log into the app. They need to fill in the demographic information and upload it as required, so they can enter the questionnaire module.

Pediatric Patient-Reported Outcomes Measurement Information System (Pediatric PROMIS)

There are two entrances in the questionnaire module as is showed in Figure 3 (3a-3b). One is for pediatric patients aged from 8 to 17 years old and who are able to report by themselves, while the other entrance is for parents of pediatric patients aged
from 5 to 7 years old or pediatric patients who need help from parents to report.

There is a voice guide, once users enter the questionnaire module, “Welcome to Pediatric PROMIS, please respond to each question or statement by choosing an item according to the feeling of the past 7 days”. The interface of the voice guide page is showed in Figure 4 (4a-4b). There are eight short questionnaire forms: Physical Functioning-Mobility, Physical Functioning-Upper Extremity, PainInterference, Fatigue, Depression symptoms, Anxiety, Peer Relationships, and Anger. If the title button of the short form is gray, the user does not need to answer that form. In other words, users can answer any of the short forms with a colored title.

When all the items of one short form are answered, feedback will be provided to the user regarding the current status and care suggestions. We have added audio assistance in this app. If the pediatric patient cannot fully understand the words of any item, he/she can click the cartoon rabbit in the left corner as shown in Figure 5. The item will then be read out loud to him/her. We tried to make sure that the pronunciation and intonation of the voice have neutral emotion, so it does not affect the response of pediatric patients.

Basic function of administration portal

Three rounds of feedback and modification of the administration portal were conducted before it was finalized. There are two types of administrators: the super administrator and the sub-administrator. The super administrators have access to all functions of the administration portal, while the sub-administrators do not have access to the management of administrators. Every administrator has a specific username and password. Sub-administrator’s username and password are assigned by the super administrator. The super administrator has access to all of the user data, while the sub-administrator has access just to data that he/she has collected.

The administration portal lists all the demographic information that users entered. Administrators can download the information as a comma separated values file, which can be opened/imported by Microsoft Excel and almost all statistics packages. The frequency data of some demographic information can be view directly as a pie chart in the administration portal. The administrator can send specific questionnaire forms to specific participants. User ID, child’s name, survey time, short form name, total scores, and total standard scores of the short form are listed in the administration system. The total standard scores are calculated according to the PROMIS Scoring Manual [10]. The administrator can also see the score of a specific item of any short form. These data can be exported to most statistical software.

The results of the usability evaluation

A total of ten pediatric patients, five parents, and two nurses participated in this usability test. The pediatric patients were aged from eight to thirteen years old. Five of them were boys.
They were diagnosed with a kind of cancer and were currently under treatment. The parents were aged from twenty one to thirty-three years old. Their children were aged from five to seven, and were diagnosed with cancer. Three of the parents were female. Two nurses were aged from 32 to 43. Both of them were female and had a college degree. Their years of working experience with pediatric patients ranged from 10 to 22 years.

After testing the app, the pediatric patients and parents felt that there was no difficulty in completing this process. All participants felt that this app was easy to use and the interfaces were friendly to children. No pediatric patients felt that the audio of the eight short forms’ items affected their response to questions. The administration portal recorded all the data accurately. Nurses who tested the administration portal thought that the interfaces were simple, and it was convenient to download the data for further analysis. They spoke highly about the different ways of downloading survey results because they satisfy different aims of studies. Overall, the app and administration portal met the demand of researchers and clinical nurses. Moreover, the app was easy to use and did not add burden for pediatric patients or their parents.

Discussion

Researchers began to collect survey data through the internet years ago [11-12]. Substantial data collection efficiency, low cost, and widespread availability of internet access among diverse groups are stimulating an increased usage of web-based surveys [13]. However, while a mobile phone is now essential to people’s daily lives, the research literature on using mobile apps for survey research is sparse. Although both the cost and time to program apps are high, the cost and time to collect data of a large number of participants are low [8-9]. Therefore, the app is a promising tool to collect longitudinal data because users have their own ID number and username.

The target users of this app are pediatric patients aged from 8 to 17 years old, and parents of pediatric patients aged from 5 to 7 years old. Our research team has been authorized to translate the PROMIS Pediatric and PROMIS parent proxy report short forms into Simplified Chinese. By including these two scales, this app enables researchers and practitioners to measure the quality of life and symptoms of children in different age groups. Based on the preference and interest of children, all the interfaces of the app were designed in cartoon styles. Cartoon images of a rabbit, bear, and giraffe were designed to be appealing to children. The lovely cartoon images may reduce their response burden and sense of boredom in answering the questionnaires. Some children even thought it was interesting to answer the questions because they loved the cartoon interfaces.

Due to chronic disease and treatment, some children cannot attend school like other same-age children. Some of them are undereducated to read all questions in the survey. Therefore, we added audio assistance for all items in the PRO survey. Pediatric patients usually use this app in the wards. Due to the noisy environment of wards, children tend to focus on the content of the items more than the pronunciation or intonation of the audio assistance. To some degree, the audio feature also adds interest to the survey.

The web-based administration portal collects and stores all the data users uploaded. The data can be easily downloaded in different forms for further analysis with statistical packages. The super administrators are researchers in our research team and have access to all the data. According to the authorization we received from PROMIS Health Organization, other Chinese researchers who want to use this app need to be approved by both PROMIS Health Organization and our research team. Approved researchers will receive sub-administrator status to collect and access their own data. With our super administration role, we will be able to perform multi-site PRO research in the future.

Conclusion

This study described the process of developing a smartphone app to monitor pediatric patients' reported outcomes. The multidisciplinary research group held group discussions to clarify the app functions of the app and administration portal. Several rounds of feedback and modification were conducted to finalize the app and its administration portal. The results of the usability study showed that the app was well accepted by target users. We conclude that the App and its web-based administration portal are with good usability, and can be applied for clinical research in regards of pediatric patients' self-reported symptoms. Smartphone apps have the potential to collect survey data with high efficiency. This app is promising to promote the use of C-Ped-PROMIS in assessing the quality of life and symptoms in pediatric patients.

I Got 99 Problems, and eHealth Is One

Sofie Wasse, Vivian Vimallund

Abstract

Many eHealth initiatives are never implemented or merely end as pilot projects. Previous studies report that organisational, technical and human issues need to be properly taken into consideration if such initiatives are to be successful. The aim of this paper is to explore whether previously identified challenges within the area have remained in the Swedish eHealth setting or whether they have changed. After interviewing experts in eHealth, we present a classification of areas of concern. Recurrence of previously identified challenges was found, but also new issues were identified. The results of the study indicate that there is a need to consider organisational and semantic issues on both national and international levels. Legal and technical challenges still exist but it seems even more important to support eHealth initiatives financially, increase practitioners’ knowledge in health informatics and manage new expectations from patients.

Keywords:
Health Services; Telemedicine; Medical Informatics

Introduction

eHealth is part of the field known as health informatics, which arose from the established field of medical informatics [1]. Ever since the definition of eHealth was first presented by Eysenbach in 2001, authors have provided additional definitions to capture the on-going development of this growing field. Pagliari et al. [2] draw upon the foundational definition and define eHealth as: “...the organization and delivery of health services and information using the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a new way of working, an attitude, and a commitment for networked, global thinking, to improve health care locally, regionally, and worldwide by using information and communication technology”. We note the focus on the delivery of electronic health services and information to improve healthcare in various ways.

Nowadays, there is pressure to reduce costs in healthcare while the quality of service delivery to an ageing population is to be maintained [3; 4]. Healthcare organisations face several challenges, such as an increased number of elderly patients, a rise in chronic diseases and a lack of personnel [5; 6]. eHealth has emerged as a solution to the challenges, and it is expected to meet the growing demand on healthcare delivery, improve quality, expand capacity [7; 8], increase access to healthcare information and foster collaboration within and between organisations [9]. With this background, governmental and private institutions have supported the funding of eHealth initiatives in an attempt to solve these problems [10]. However, several eHealth initiatives terminate as pilot projects or are never implemented at all [11; 12]. It is estimated that 70% of eHealth projects fail to achieve their goals [13]. These failures have been studied and described in previous studies [13; 14; 15-17]. The current literature and research in this area demonstrate that organisational change and the adjustment of work processes are crucial when eHealth solutions are to be successfully implemented [15; 16; 18-23]. A number of studies also highlight the importance of system usefulness, ease of use and flexibility, as well as individual factors, including user training, skills and user involvement [21; 24]. A model has been presented which addresses the problem of health information system (HIS) failure. This model includes dimensions related to information, technology, organisation and resources [25]. Despite this body of knowledge which has been gathered from the analysis of different healthcare systems and countries, eHealth initiatives continue to fail [11].

The aim of this study is to explore whether previously identified challenges within the eHealth area are still valid in the Swedish eHealth setting, or whether these challenges have changed. This information can be used by decision-makers as they prioritize and identify short-term and long-term goals and develop strategic plans.

Methods

A number of decision-makers and experts in eHealth were interviewed with the aim of identifying current and future challenges that the provision of eHealth in Sweden faces. The respondents included seven representatives working with the forthcoming Swedish eHealth strategy. These representatives included administrative authorities, the ministry, employers’ organisations and trade organisations. They represent the broad number of actors that influence the evolution of eHealth in Sweden. The organisations that were represented were the Swedish Association of Local Authorities and Regions, the National Board of Health and Welfare, the Ministry of Health and Social Affairs, the Swedish Society of Nursing, the Swedish Association of Health Professionals, Famna and the Trade Association for the Research-based Pharmaceutical Industry in Sweden (LIF). Each respondent was contacted by email to arrange for these interviews at their offices.

The questions that were asked during the interviews covered areas such as the primary challenges and the future trends of Swedish eHealth. Background questions were also asked regarding the organisation’s role in Swedish eHealth, who the important actors in the area were and significant milestones within Swedish eHealth. The interviews were performed by the first author and lasted between 40 to 65 minutes each. They were recorded and later transcribed verbatim. In addition, notes were taken during the interviews. The questions that were asked are presented in Table 1.
Data analysis

The analysis of the interviews was performed by means of inductive content analysis, as presented by Graneheim and Lundman [26]. Content analysis is a systematic way of describing and analysing written and verbal communication [27]. The inductive approach, where themes are derived from the data, is suitable when little is known about the studied phenomena or when previous knowledge is fragmented [28]. Initially, the transcripts were read through several times to gain an overall sense of the entire data-set. Then the remarks about challenges were extracted and compiled into a section that constituted the unit of analysis.

Further to the above, the analysis was conducted in a number of steps. First, the text was divided into meaning units, i.e. “sentences or paragraphs containing aspects related to each other through their content and context” [26]. Second, each meaning unit was ‘condensed’; referring to the process of shortening the meaning units while still preserving the core meaning [26]. Third, the condensed meaning units were labelled with a code. Fourth, the codes were interpreted and compared across each other so as to create mutually exclusive sub-themes. A theme can be described as “an expression of the latent content of the text” [26]. By reflecting and analysing, the initial sub-themes were reduced into fifteen sub-themes that all focused on challenges. Finally, we reflected on the sub-themes and read literature pertaining to these sub-themes and to the current state of eHealth [5; 29]. This resulted in headings that seemed to unify the sub-themes into six themes. The meaning units were read through again and nothing that contradicted the themes could be found. Even if the analysis is described as a linear process, the process was iterative and involved going back and forth during the analysis.

Trustworthiness in content analysis can be described in terms of credibility and transferability [26]. To achieve credibility, we have illustrated how sub-themes and themes are related and we present representative quotations from the interviewees that support the opinions expressed during the interviews. Transferability has been facilitated by describing the context, the data collection and the analysis process, as well as providing a rich description of the findings. In addition, the results of the analysis were discussed by the first and second author so as to ensure agreement. In the next section, we present a classification of areas of concern.

Results

From the interviews, six main areas of concern (themes) and fifteen sub-themes were identified. The respondents described issues related to different levels of interoperability, the need for more resources and placing the patient at the centre. The findings are presented in Table 2 and are described in detail with quotations from the respondents.

Organisational interoperability

The importance of organisational interoperability involved managing organisational change and development, collaborating over organisational boundaries and finding common goals. The respondents described the importance of not managing eHealth initiatives as information technology (IT) projects, but, rather, as changes in business processes, structures and cultures. IT was not described as the challenging part of eHealth, compared to the organisational change that it entails. One respondent described it in the following terms: “…the technical issues are not the difficult or big problems, but changed business processes, attitudes and change management, that type is much, much bigger issues” (f).

The respondents also talked about the need to collaborate across organisational boundaries, the necessity to coordinate this collaboration and to establish spaces where actors can meet and collaborate for innovation. The same respondent said: “I think it is really great, and many people are bothered about it, they say it is so unclear in Sweden, that we have so many actors within the area of eHealth and so on. But I think that it is fantastic, I would not want another situation, it is great that it is that many. However, we might need to work a bit on coordinating different activities, collaborate to get the most out of it…” (f). The importance of having common goals was particularly stressed by the respondents. They mentioned that there is a need to have a unified picture of the future, that local ideas and goals can hamper the development of eHealth, and that everyone needs to move in the same direction. One respondent said that: “…it is not possible that one actor pushes the development. Because everyone is needed…so the difficult part, or what I see as the most important thing, is that we all move in the same pace” (b).
Technical interoperability

Another matter that was mentioned during the interviews were a number of technical challenges, including communication between different information systems and usability. The lack of communication between information systems was described as a problem that results in data redundancy, referring to the need to document the same information twice. “It is someone that actually sits and interprets the information in the EHR [electronic health record] and transfers it manually to a web formulary” (a). The same issue was exemplified with the use of quality registers: “We need to establish an automated transfer of information. You document in the EHR and then it should automatically be able to transfer that information to the quality registers or other administrative systems that are for quality improvement and similar things” (d). In addition, the respondents talked about achieving standards of ‘high usability’ in eHealth services and the importance of services that are supportive instead of interfering in work processes. However, technical interoperability was no longer viewed as a main barrier, compared to organisational, semantic and legal interoperability: “…well, the technical interoperability is really the least problem today” (a). “The technical part is simply an element in the whole and it is not that challenging” (f).

Legal interoperability

The respondents also mentioned the importance of legal interoperability and that laws and regulations need to adjust to accommodate the digital evolution. This also involved balancing across the fine line of integrity and service innovation. “But it falls on the legislation, that the laws are as they are today” (a). One respondent exemplified this point with a reference to the Swedish Data Protection Authority: “…they only have to look at one side of the issue. As an authority, they never have to weight both scales as all others have to do. And we can say that, well maybe there is a risk for the patient, an integrity risk in one scale, but there is actually a medical risk in the other scale” (g).

Semantic interoperability

All of the respondents stressed the importance of achieving semantic interoperability. This involved the regulation of the exchange of information between primary care and hospitals through a set of principles that includes common terms, concepts and a national information structure. One respondent described semantic interoperability as being the most important issue: “You have this semantic interoperability with these common terms and concepts and information structure. That is such a big problem” (a). Several respondents claimed that a unified information structure is the necessary foundation for information sharing, the development of innovative services and new ways of working.

The need for additional resources

The Swedish eHealth area was described as being in need of more resources, both in terms of financial needs, but also in terms of knowledge of how informatics and organisational healthcare issues are to be solved. Today, the various Swedish regions invest 3% of their budget on IT/IS and eHealth [30]. The respondents reported that they found it remarkable that a knowledge-intense industry, like healthcare, does not spend more resources on eHealth: “You need to build structures and set aside time for it. It costs money and it is an underfinanced area in total, out in the regions” (d). In addition to the above observation, increased knowledge about health informatics was viewed as something that should be prioritized: “…I believe that there are too few people that understand both IT quite well, understand the industry, but also understand IT so to say on a higher level...so you can be really good at a small part of this, but to like see all these flows” (g).

The patient at the centre

The respondents also spoke of the importance of acknowledging the patient and dealing with new expectations from citizens and patients. The healthcare sector was described as ‘paternalistic’ and pushing the patient into the organisational structures of healthcare. One respondent said that: “...it is a paradigm shift within primary care, that we try to somehow adjust our healthcare organisations according to the needs of our citizens, instead of adjusting the citizens into our organisational structures” (f). Another respondent talked about the ownership of information: “Well you think that it is the patient that should own the information. And that trend is also a huge challenge and an important culture issue. If we succeed with it, what will the impact be then?” (c). Patient empowerment was also mentioned as an area of concern: “One area that we support, as an organisation, is the patients’ ability to influence their own health and to gain as much knowledge as they want” (d).

Discussion

The aim of this study was to explore whether previous reported challenges in the eHealth area are still valid in the Swedish context, or whether novel challenges can be identified. The results show that today’s challenges focus on issues of interoperability, the need for additional resources and the need to manage new expectations from patients.

The most important challenge that eHealth faces seems to be organisational interoperability. The respondents stressed the importance of organisational change in relation to eHealth and the re-engineering of organisational processes. From surveying the literature, we note that individuals, tasks and technology need to fit smoothly together when eHealth services are introduced into an organisation [22; 23]. There are several reports on the importance of change management during implementation of eHealth initiatives [17; 21; 31]. Other well-known challenges, include technical interoperability that has been part of national eHealth strategies for many years [32; 33]. While our findings indicate that technology development is still a challenge, it seems to be less troublesome than before. As argued by Haux [20], this change could be identified as early as the 1990s, when organisational issues and change management became the main focus, instead of technical issues.

Further to this, certain changes in the relevant regulations and laws that govern the digital evolution, remain a barrier for the successful of eHealth. This is not a new state of affairs: legal issues constituted a barrier for the implementation of patients’ digital access to EHRs in Sweden in 2003. Then, the law stated that digital access to healthcare registers could only be given to those who needed such access in order to carry out their work. Consequently, it was deemed that the patient did not need the information, since the patient was not classified as an employee, and the project was considered illegal [34]. A common information structure and shared concepts were seen as the foundation for realising the potential of eHealth. Semantic interoperability enables organisations to ensure that the exact meaning of information is understood at the moment of exchange with other actors [29]. During the last several years, a number of political incentives have been proposed in an effort to foster semantic interoperability on an international level [5; 29].

The need for additional resources was also mentioned, including both financial and knowledge resources. The respondents stressed the prerequisite of professionals that...
understand how information and communication flows can be improved by eHealth. Education and training in health informatics and HIS skills have been acknowledged previously [16; 20] and discussed at MEDINFO and AMIA Symposia for several years. However, this issue seems to be less prominent in eHealth policies [35].

In summary, the challenges that were identified in the present study are well-known, and it seems as if they are the same as they were ten to fifteen years ago. However, a number of novel challenges have also emerged. When health information systems have moved on from focusing on local solutions, in, for instance an individual department, to regional or global systems [20], then new challenges seem to arise. As an example, Sweden has implemented a national patient summary as a step towards making EHRs interoperable across the different Swedish regions [36]. Today, the challenges of interoperability and organisational change seem to transcend organisational and national boundaries, and are thus not limited to the individual organisation that is to develop and implement an eHealth service. For instance, the respondents mentioned a lack of spaces where different actors can meet so that they can collaborate for innovation and share common goals. In addition, there seems to be an increasing number of new expectations from patients and citizens. In the beginning, health information systems were primarily developed to support healthcare professionals in the execution of their work [20]. But since then, several solutions have been developed to also support patients [37; 38]. Today’s society is more digitalised compared to the time when eHealth was originally introduced in the 1990s, and thus the expectations from patients and citizens will be a crucial question to manage.

This study has a number of limitations that need to be taken into consideration when the reader interprets the results. First, the number of interviews was small and this limits the possibility of applying the results in other settings. An additional quantitative study could, therefore, provide further insights into the delivery of eHealth services. The respondents include representatives who work on a strategic level; future studies should also include representatives from other areas, such as healthcare professionals and entrepreneurs, for example.

Conclusions

eHealth services are globally described as an opportunity where the quality and access to healthcare can be improved and where patients can engage in understanding their own health situation [5; 6]. Previously identified challenges indicate that organisational as well as technical and human issues need to be properly dealt with if eHealth is to be successful [21; 22; 24]. Nevertheless, our study reports that these challenges still exist. Despite the public eHealth context of Sweden and the several existing eHealth policies that have been adopted in this country [39-41], the challenges that face the successful delivery of electronic health services and information to improve healthcare are similar. No strategic plan seems to be good enough, if it is not financially and administratively prioritized. Today, change management is reported as the most important issue which needs to be dealt with, along with semantic issues. These challenges are not restricted to individual organisations, but exist across organisational boundaries. To achieve success in eHealth initiatives seems easier said than done. Fortunately, the previously identified challenges and priorities within the area of eHealth remain valid. However, the expectations that are made of eHealth services need to be realistic [42] because several problems need to be dealt with in conjunction with the development and implementation of eHealth services. If the full potential of eHealth is to be realised, we believe that it is necessary to develop clear guidelines on both national and international levels, and that these guidelines clarify the collaboration among different actors and the implementation of eHealth services. Only then is it possible to learn from the past and develop the administrative, organisational and social structures that are needed.

Acknowledgements

The authors express their appreciation to the individuals that participated in the interviews.

Abstract

Diabetes is one of the major burdens in health care, but could be controlled if the relevant data is well-managed. Referring to current successful cases, we designed a framework for the interoperability and integration of medical data in compliance with both archetype and reference information model specification. The clinical data model (CDM) was designed on the basis of OpenEHR archetypes and self-made patient generated health data (PGHD). Integrating healthcare enterprise (IHE) protocol was taken into integrating different modality data. After terminology mapping, the personal health record could be transferred and shared in different clinical information vendors complying with HL7 standards. Many fragment data such as blood glucose and gene data were also integrated to system. Those patients suspected of higher risk of diabetic retinopathy (DR) were grouped as case and other patients could be filtered as control cohort. Furthermore, the framework could be further developed for precision medicine.

Keywords:
Diabetes Mellitus; Health Level Seven; Precision Medicine

Introduction

Diabetes, a chronic metabolic disorder of blood sugar, cause a variety of complications including heart disease, stroke, chronic renal failure, foot ulcers and retinopathy, if blood sugar is not be controlled at normal level. By 2015, there were about 415 million people suffering from diabetes in the world, of which 90% are type 2 diabetes. Between 2012 and 2015, about 1.5 to 5 million people worldwide died from diabetes each year, resulting in direct economic losses of about $612 billion\cite{1-3}. With rapid development of high-throughput biotechnology, various types of omics and systematic methods, precision medicine is becoming a new paradigm of future medical development. As the next generation of diagnosis and treatment technology, precision medicine has important theoretical and practical significance.

Precision medicine is a biomedical strategy of health care to improve patient-specific and individualized diagnoses, medical decisions, medications, therapies, and prognoses and to make the life quality better\cite{4-6}. For diabetes management, precision medicine services based on big data will allow for patients to be served with appropriate treatment at the right time. Therefore, effective secondary use of relevant health data is a critical step. In recent years, hospitals, patients and doctors have paid more and more attention to personal health management. The opening and sharing of medical data has become a hot topic in the world. The United States “Blue Button” took the lead in achieving the opening of personal medical data. Users can download their own medical data online, master more personal health information and family medical information. According to statistics, more than 107 million people use “Blue Button”, more than 250 million users registered for Blue Button, more than 5.2 million “Blue Button” files were downloaded, and more than 84 million patients choose to use Secure Messaging. In addition to Blue Button, the United States Partners HealthCare Group (PHG) health service system can also provide patients with records integrated with disease, medications and test results. The OpenNotes project allows patients to access physician diagnostic notes online.

There are many diabetes information management systems (DIMS). However, existing DIMS with standalone data repository has the limitation of interoperability. In this paper, we propose a new diabetes framework using the clinical data model (CDM)\cite{7-10} and following health level 7 (HL7) standards, an integrating with data from third-party systems such as blood glucose, fundus image, etc. Additionally, cohort grouping were analyzed and developed for precision medicine.

Methods and Results

System design and implementation

The development environment of our study were as follows: CPU: P4 1.8GHz; RAM: 256MB; Operating system: Windows 10; Database: SQL Server 2000; Server: Local server. The following program was required to run the website normally: Microsoft Visual Studio 2013; Runtime environment: CPU: Intel Pentium M 1.88GHz; RAM: 1GB; Hard disk: 60GB. The system was designed as browser/server (B/S) structure and with a simple portal interface for user. After successful registration, users can login into the website and upload their health data by manual entry or direct file upload. The ability to download data as a separate file for purposes of sharing and integration with other information vendors were also developed. (Figure 1)
Clinical data model (CDM) and template design for T2DM

CDM provides a logical model for representing clinical data elements normalized using standard terminologies and coding systems. Different from previous CDM[11-14], patient generated health data (PGHD) such as self-monitored blood glucose detected using portable glucometer or fundus images taken by digital fundus camera were considered in our CDM design. The CDM is defined using a Constraint Definition Language (CDL) that can be compiled into computable definitions. For example, a CDM can be compiled into XML or semantic web resources description framework (RDF) to provide structured model definitions. Furthermore, the CDM prescribe that codes from controlled terminologies be used as the values of many of their attributes. This aspect, in particular, enables semantic and syntactic interoperability across multiple clinical information systems. In this study, CDM design was implemented with OpenEHR archetype and templates tools. A sample CDM data element for representing allergies is shown with different attributes. The “orderable item value set” is a set list controlled codes appropriate to represent orderable medications (e.g., RxNorm codes). The attribute dose represents the “physical quantity” data type, which contains a numeric value and a code for a unit of measure (Figure 2).

Interoperability

As proposed in HealthIT.gov’s eHealth Incentive Program (HITIP) and Health IT Standards Committee (HITSC), the interoperability of patient’s health data between different vendors is important in meaningful use (MU) to ensure that the clinical data and algorithmic criteria are represented in a consistent, unambiguous and reproducible manner[15-18]. The complexity of the clinical domain requires a clear definition of the formal description of knowledge and information structure. To handle this, we took HL7 clinical document architecture (CDA) as a document reference model to define our templates. These templates are usually defined in the text implementation guidelines or in the complex format made by clinicians. Simultaneously, standard clinical term codes were bound to their information structure. (Figure 3 and Figure 4) We further validated our interoperability by integrating standard third-party data in our following experiments.

A popup dialog prompts user to choose a path to save the XML document, and each patient’s record like patient name create time.xml could be exported in CDA format for data interoperability (Figure 5).
Phenotyping, querying and grouping

Phenotype is key to big data within a platform achieving precision medicine [19]. Identification of patient cohorts for conducting clinical and research studies has always been a major bottleneck and time-consuming process [20]. To meet this requirement, increasing attention is being paid to leverage electronic health record (EHR) data for cohort identification [21]. In particular, with the increasing adoption of EHRs for routine clinical care within the U.S., as a result to Meaningful Use, evaluating the strengths and limitations for secondary use of EHR data has important implications for clinical and translational research, including clinical trials, observational cohorts, outcomes research, and comparative effectiveness research.

In the recent past, several projects, including eMERGE, SHARPn, and i2b2, have developed tools and technologies for identifying patient cohorts using EHRs. A key aspect of this process is to define inclusion and exclusion criteria involving EHR data fields such as diagnoses, procedures, laboratory results, medications as well as logical operators. Therefore, we developed a “query and grouping” module and scalable informatics infrastructure for normalization of both structured and unstructured EHR data into a unified, concept-based model for high-throughput phenotype extraction. The phenotyping algorithms were developed by the domain experts and clinicians along with informaticians. After de-identification of patients’ privacy information, executable Drools rules scripts and the rules engine that executes the scripts were used to generate evaluation results and visualization. Domain experts and IT personnel performed extract-transform-load (ETL) of “native” clinical data from the EHR systems into a normalized and standardized CDM database that was then accessed by the JBOSS rules engine for execution (Figure 6).

Blood glucose data integration based on HL7 V2 message

In this experiment, Mirth Connect was utilized as an interface engine for HL7 data transmission and integration. To validate the HL7 message, 7edit was used to validate and parse HL7 message in this test (Figure 7).

Gene reports sharing and integration based on IHE-LAB

IHE-LAB specification is a framework to carry out the integration between laboratory examination and EMR. According to CDA specification, we edited relevant procedure with the help of XML parser to conduct any other operation or save medical records into local database. CDA has an extensive range of vocabulary, also includes a number of other organization vocabulary, which is recognized by the HL7 specification, such as logical observation identifiers names and codes (LOINC), systematized nomenclature of medicine - clinical terms (SNOMED-CT), etc. HL7 reference information model (RIM) is the model basis of HL7 standards which formed on the CDA document stated. XML technologies inherited implementation of the HL7 specification (ITS), which produces CDA data types. On the other hand, CDA does not consider transmittal modes that happen to be a part of HL7 standards. Regarding clinical documents, CDA specifications complement the HL7 standard. In this research, a diabetic retinopathy gene test report (DR-GTR) in compliance with CDA format was created and such GTR was integrated in the form of continuity of care record (CCR) into our system (Figure 10).
Users could view fundus images by visiting web accessible transmitted into our previously established eye-PACS[22]. and communication in medicine (DICOM) format, then jpg format of images were transformed into digital imaging Co., Ltd, China) was used to obtain fundus images. The raw within the system (Figure 11).

Portable fundus camera (Suzhou KangJie Medical Equipment Co., Ltd, China) was used to obtain fundus images. The raw jpg format of images were transformed into digital imaging communication in medicine (DICOM) format, then transmitted into our previously established eye-PACS[22]. Users could view fundus images by visiting web accessible web access to DICOM persistent objects (WADO) protocol within the system (Figure 11).

Figure 11 - Fundus images were integrated and shown (up: fundus image obtained; down: fundus image integrated)

**Fundus image integration based on IHE-XDS**

**Portable fundus camera** (Suzhou KangJie Medical Equipment Co., Ltd, China) was used to obtain fundus images. The raw jpg format of images were transformed into digital imaging and communication in medicine (DICOM) format, then transmitted into our previously established eye-PACS[22]. Users could view fundus images by visiting web accessible web access to DICOM persistent objects (WADO) protocol.

**Discussion**

Our team has previously developed an EHR system for local Nantong residents with about 6 millions records. However, as more and more fragment data from diabetic patients are now being obtained from different information vendors, a centralized data repository is not flexible enough to afford increasing amounts of fragment data. The management of such data from all aspects is therefore in need of fully integration of different standalone vendors. Many institutes have launched studies on such sharing platform developments. The CDA standard that specifies the structure and semantics of clinical documents used for exchange was adopted for integration. Due to the ability of clinical descriptions, flexibility and machine readable, CDA template was implemented as data specification for other systems[17; 23; 24]. However, archetypes based model have been proved to be more flexible for system architecture and have been taken into practice in many health care system development[25; 26]. The OpenEHR specification is an open EHR architecture, which is developed by the OpenEHR institutions, and its goal is to achieve the sharing of medical information within systems[27]. The two-layer model is designed to loosely couple the medical model and software engineering[18; 28; 29]. Our system adopts such two-layer model and collects, opens, shares and analyzes patient’s health care data to help patients with diabetes monitor their all-weather, full life-cycle of health indicators. The value of the framework is not only that people with diabetes can obtain data from EHRs, they can also share and link their other modalities of data into EHRs, thus contributing to faster and more accurate management of diabetes.

Since precision medicine has been proposed, a number of research projects have been granted to imitate cohort studies with large sample size and abundant health data, which stimulates the need for development of high-throughput output data systems and electronic platforms. SHARPn, i2b2 and transSMART are such influential open-source platforms that could be integrated with genomic data and are important for clinical trials investigations, and meaningful to precision medicine. Similarly, we developed the “query and grouping” module referring to i2b2 and SHARPn project. Moreover, we made the EHR data standardization via mapping and interface for transforming, that is, uniform terminology was used to facilitate the researchers who choose concepts to query on. By doing so, clinicians could start grouping and cohort research quickly and easily. The large-scale precision medicine investigation relies on phenotyping algorithms, and there have been two challenges in particular, that is, local data elements in an EHR may not be natively represented in a format consistent with the QDM including the required code systems and value sets; and an EHR typically does not natively have the capability to automatically consume and execute phenotype definitions logic. In this study, we tried to map local data elements to SNOMED or ICD codes to solve term definition disambiguation.

Based on our framework, patients with diabetes could obtain their own medical records to effectively carry out self-health management and improve the quality of medical treatment. Doctors could provide personalized care to patients with diabetes, reducing the risk of misdiagnosis, thus saving medical costs and increasing benefits. The innovation in this study relies on PGHD CDM, since it could provide potential solution to enabling prospective cohort design by altering tests and to patients with feedback reports. Although our framework can effectively integrate data in heterogeneous information systems, including the integration of clinical data, we also need to consider the information integrity and confidential transmission and other security issues. Additionally, we developed some visualization plugins to allow clinicians to better analyze diabetic data. The ultimate goal is to achieve a framework for secondary use of EHR data for high-throughput phenotyping in diabetes. Furthermore, we will develop the computer aided decision analysis module[30] based on our diabetes platform to carry out the trial and investigation in the community, and improve our system via the study of the feedback information.

**Conclusion**

In conclusion, iT2DM could facilitate data sharing and integration of diabetic patients, and could be further developed for precision medicine specified on diabetes management.

Development of Home-Based Sleep Monitoring System for Obstructive Sleep Apnea

Peirong Wu, Guan-Ting Chen, Yanyan Cui, Jin-Wei Li, Terry B.J. Kuo, Polun Chang

Abstract

Obstructive Sleep Apnea (OSA) has been proven to increase the risk of high blood pressure, heart attack, stroke, obesity, and diabetes. If people would like to know whether they are suffering from this sleep disorder, they need to go to particular hospital with which a sleep center that could perform polysomnography (PSG); however, for most people, this is not convenient. Consequently, the goal of this study is to develop a convenient, lower priced, and easy-to-use home-based sleep monitoring system. The researchers have developed the “Sleep Healthcare Management System” for OSA patients and healthcare providers. It combines smartphone and wearable devices that can perform real-time sleep monitoring. Healthcare providers could apply their professional knowledge to provide customized feedback via a web application. When the patient is diagnosed with an abnormal sleep health condition, healthcare providers may be able to provide appropriate and timely care.

Keywords:
Polysomnography; Smartphone; Obstructive Sleep Apnea

Introduction

Obstructive Sleep Apnea (OSA) is a common disorder in the population [1]. The National Heart, Lung and Blood Institute of American National Institutes of Health (NIH) indicated that untreated sleep apnea could increase the risk of hypertension, heart attack, stroke, obesity, and diabetes, etc.

OSA is one type of sleep apnea. According to different symptoms, there are three types of sleep apnea: OSA, central sleep apnea (CSA), and mixed sleep apnea. Among these types of sleep apnea, OSA is the most common. The prevalence of OSA was a mean of 22% in men and 17% in women [1]. The standard test for the diagnosis is polysomnography (PSG). This test would monitor multiple physiological signals of sleeping patients overnight in order to measure the apnea-hypopnea index (AHI). According to the American Academy of Sleep Medicine (AASM), the diagnosis of OSA is AHI $\geq 5$ with symptoms such as daytime somnolence, fatigue, insomnia, mood disorders, and cognitive impairment, or cardiovascular comorbid conditions [2].

However, PSG is not easily accessible in Taiwan, people need to go to the sleep center to do the examination. The subject must be settled with many sensors for collecting physiological signals during the test, the subject often feels uncomfortable; furthermore, the subject usually has only one night to do this test, PSG may not be suitable for those particular sleep disorders which should take more time to be tracked.

Based on the above reasons, the researchers want to develop a convenient, low price and easy-to-use home-based system. Thus, people could realize their sleep health condition in an easy way.

Methods

The researchers designed a home-based sleep monitoring system, the “Sleep Healthcare Management System” [3-7]. This system includes two subsystems: A front-end subsystem “Sleep Healthcare Management System-Patient” and a back-end subsystem “Sleep Healthcare Management System-Healthcare Provider”. At the front-end subsystem, we would develop a mobile phone application for patients to collect their physiological signals and view these physiological signals in a visualized way. At the back-end subsystem, we would develop a real-time feedback system, which is a web application for healthcare providers to view physiological signals of the patients and set the content of feedback that would be sent to the patients. The entire system structure is shown in Figure 1. All functional requirements of the front-end subsystem and the back-end subsystem are shown in Table 1 and Table 2 respectively.

Evaluation of the Sleep Healthcare Management System

In this system, the sleep-position trend is the most important reference of the sleep diagnosis. The accuracy of the sleep-position detection algorithm reflects the reliability of this system. Therefore, the researchers designed a controlled trial followed by a “sleep-position-detection evaluation procedure” (Figure 2) to evaluate our system.

In this controlled trial, all recruited subjects will be assigned to the experiment group.

During the trial, the control group would use a timer to record the moment of every sleep-position changes; the experiment group would wear the breath tracker and follow the “sleep-position-detection evaluation procedure” to change their sleep-position.

After that, according to the Karl Pearson’s Coefficient of Correlation, we could calculate the accuracy of the sleep-position detection and the coefficient of correlation of the sleep-position detection.

Results

According to the system design and all functional requirements, we developed a home-based sleep monitoring system called “Sleep Healthcare Management System”. This system includes two subsystems: “Sleep Healthcare Management System-Client”, which is a mobile phone application and “Sleep Healthcare Management System-Healthcare Provider”, which is a web application.

Patients could view their physiological signals which were collected by the SpO2 device and breath tracker in a visualized way via their mobile phone; the healthcare provider could view multiple physiological signals which were uploaded by patients on a web application. The detail of these two subsystems will be described below:
Front-end: Sleep Healthcare Management System-Patient

Android is the most popular mobile OS and it provides a free, open source, cross-platform development environment. Besides, numerous open source projects in Android support arithmetical and graphical functions. Also, the developers could use its official development tool: Android Studio to develop applications in a convenient way [9].

Therefore, we adopted Android as the mobile OS of this mobile phone application and Android Studio 2.0 as the development tool; we run this application on mobile phone, which supported Android version 4.3 or later.

This mobile phone application contains 7 modules: dynamic scale, sleep management, sleep-position trend, data collection, SpO2 device, device management, breath tracker (Figure 3). Among these 7 modules, SpO2 device module and breath tracker module need to manipulate with wearable devices for collecting the physiological signals of the patient.

Sleep-Position Trend Module

This module is used for presenting the change of the patient’s sleeping position (e.g. supine, right-side, left-side, prone, stand) in a visualized way. The healthcare provider could view charts in different time segments (e.g. 1 minute, 10 minutes, 30 minutes, 1 hour) and export these chart (Figure 5).

During 8 hours sleep, most people would turnover up to dozens of times, even hundreds of times. Appropriate turn-over times is important reference index to health professionals. Furthermore, sleep time could be reduced. So the times of turnover is an important consideration in development.

Sleep Management Module

This module is used for presenting the change of the patient’s sleeping parameters (e.g. sleep start time, sleep end time, sleep total time, light sleep time, deep sleep time, wake up time, wake up times and sleep score) in a visualized way.

All sleeping parameters are obtained from algorithm [8] that process physiological signals transmitted from wearable devices to the data collection module of this system via Bluetooth technology.

SpO2 Device Module

This module could present real-time physiological signals of the patient: SpO2, pulse rate(PR), perfusion index (PI). In the normal condition, pulse rate equals heart rate. PI could reflect the situation of patient’s limb perfusion in a visualized way.

Breath Tracker Module

This module could present real-time physiological signals of HRV report of the patient: LF(low frequency), HF(high frequency), total power(TP), RR(R-R interval), RT(reserve time), IT(inspiratory time), IV(inspiratory volume).

Device Management Module

Patients could bind two wearable devices: SpO2 device and breath tracker, to their mobile phone via this module.

Data Collection Module

The main function of this module not only shows real-time physiological signals collected from two wearable devices on the patient’s mobile phone, but also shows the connection status between wearable devices and the patient’s mobile phone.

Dynamic Scale Module

In our system, we regard scale(questionnaire) as one type of feedback. The healthcare provider could view physiological signal charts and learn more about the sleep health condition of the patient by using scale as an evaluating tool. Because the content of scale would be a variety of forms, we separate scale as an individual module. Content of the scale was designed by healthcare professionals and saved in the remote server.

As the healthcare provider is conscious of the patient, who is under a bad sleep health condition, the scale might be sent to the patient, then healthcare provider could evaluate the sleep health condition of the patient via scale.

There are two reasons for why we called this module “dynamic” scale module: First, according to the sleep health condition of the patient at different time, the scale which this system decided to send would change dynamically. Second, when the patient finished a scale, the system would calculate a score of the finished scale for judging whether it is necessary to have another scale for evaluating the patient’s sleep health condition or not; if the score meets the scale-sending criteria, this system will send another scale to the patient.

Thus, this “Dynamic Scale” would work dynamically, it could send scale, which meets different sleep health conditions of the patient dynamically.

Back-end: Sleep Healthcare Management System-Healthcare provider

One of the main function of this web app is to perform the real-time change of the patient’s physiological signals via charts. Consequently, the efficacy of this web application becomes the most important consideration in development.

Node.js is a web application framework built on Chrome's V8 JavaScript engine. Because of its’ lightweight and efficiency, Node.js becomes a popular programming language for web development now; moreover, we could use Node.js’ open source library: NPM for trimming development time greatly [10].

Because Node.js exactly met our requirement, we adopted Node.js as the main program language of this web application and WebStorm as the development tool.

WebStorm is a lightweight yet powerful IDE, equipped for complex client-side development and server-side development with Node.js.

This web application contains 3 modules: sleep-position trend, physiological signals feedback, feedback setting (Figure 4).

Sleep-Position Trend Module

This module is used for presenting the change of the patient’s sleeping position(e.g. supine, right-side, left-side, prone, stand). Healthcare providers could view charts in different time segments(e.g. 1 minute, 10 minutes, 30 minutes, 1 hour) and export these chart(Figure 6).

Physiological Signals Feedback Module

This module is an association-rule system, healthcare providers could record clinical principles or their professional knowledge as rules(ex: greater than, smaller than, equals, between) via web application, all rules would be stored in the remote server.

According to patient’s physiological signals(e.g. heart rate, sleep-position, temperature, SpO2, sleep score), these rules are used for analyzing the sleep health condition of the patient.

If the result of analysis shows that the patient is under the abnormal sleep health condition, or the patient’s sleep health condition conforms to the rule, the feedback would be sent to the patient.

Feedback Setting Module

Healthcare providers could decide what content of feedback would be sent to patients via this module. The content of feedback would be many formats, such as text message, questionnaire and health education information. Healthcare
providers could use questionnaires to help diagnosis and know more about the sleep health condition of the patient.

Figure 3 – System Structure: Sleep Healthcare Management System-Patient.

Figure 4 – System Structure: Sleep Healthcare Management System-Healthcare Provider.

Figure 5 – Physiological Chart: Mobile Application.

Evaluation of the Sleep Healthcare Management System

This controlled trial was conducted in Taipei City from February 23, 2016 to March 1, 2016. We recruited 9 subjects who were attending university (20–35 years old; 2 male; 7 female). All results are shown in Table 3. In general, data from the experiment and control group were consistent (Figure 7). However, there were problems noted with the results for the second, third, and fourth subject.

As for the second subject and the third subject, their accuracy of sleep detection is 0.81 and 0.74 respectively. The accuracy is also lower than other subjects because the breath tracker they wore received signals with latency. If we are regardless of the phenomenon of signals with latency, the recorded state of both the second subject and the third subject is correct.

The accuracy of the sleep detection of the fourth subject is 73.51, much lower than other subjects. Because of the breath tracker she wore was interfered by noise at the beginning of the test. But the breath tracker will no longer be interfered by noise after the second state of the test.

The mean accuracy of our sleep-position detection algorithm is 0.89, the mean coefficient of correlation is 0.97. The result of this controlled trial showed that our system is highly reliable.
Discussion

The limitation of this study is the small size of the pilot evaluation. One of the next steps of this study is to do a randomized controlled trial for evaluating this "Sleep Healthcare System". In this trial, the researchers would recruit more OSA patients and use a randomized program to assign these patients equally into the control group who are not using PSG and an experimental (intervention) group that are using the Sleep Healthcare System. Then the researchers would design a scale for the healthcare provider to know how efficiently and effectively this system could help them to monitor OSA patients.

Patients’ awareness of information security has increased and more attention is now paid to the privacy of personal data. How to ensure the security of data transmission and increase the reliability of system is an important question; therefore, the improvement of the security of the system would be an important future project.

Conclusions

Base on the system design, this study implemented the "Sleep Healthcare System," which is suitable for obstructive sleep apnea patients.

This system has many features such as high convenience, real time, low cost; it also has intuitive and easy-to-use interface for adjusting the settings. It allows patients to do sleep monitoring at their home and enables health providers to get the sleep health condition of patients in a fast way.

People only need one smartphone and two wearable devices; then they can complete real-time sleep monitoring at home and they can view their physiological signals in a visualized way. Thus, people could know their sleep health condition quickly.

When the patient is experiencing an abnormal sleep health condition, the remote server can send feedback immediately and the healthcare providers can be made aware of the patient’s sleep health condition, enabling them to provide care services to the patients in a timely manner. In this context, this system would be useful for people who suffer from obstructive sleep apnea and their healthcare providers.

Screening for Behavioral Risks: A Precision Healthcare Driven Approach for Chronic Pain Evaluation in Pediatric Specialty Care

Vibha Anand\textsuperscript{a}, Andrew S. Zeft\textsuperscript{b}, Steven J. Spalding\textsuperscript{c}

Abstract

We previously described an informatics tool (PROBE) to automate screening for behavioral risks for pain in children and adolescents. PROBE was deployed for a one-year pilot study in our pediatric specialty care practice. Here we describe evaluation of this tool to assess self-report of pain, chronic disease activity and behavioral risks in 109 patients who sought routine care in the busy outpatient pediatric rheumatology practice of our large healthcare system. Results show that patients who self-report poorer self-efficacy and coping skills and nighttime awakenings have significantly higher odds (8 and 5 times higher respectively) of reporting chronic pain even after accounting for their chronic disease activity. Our results show that automating screening in specialty care waiting rooms cannot only inform the clinicians of patient’s unknown risks but may even help drive the judicious use of precision healthcare resources such as cognitive behavioral therapy.

Keywords:
Chronic Pain; Pediatrics; Screening Behavioral Risks

Introduction

The medical science community has been studying pain for many decades including developing and evaluating pain questionnaires since the 1970s.\cite{1-3} However, it is not until recently that focus on prevention, education and research has become a national priority in the US.\cite{4,5} In the past, much work focused on addressing pain in life threatening settings such as cancer and palliative care.\cite{6,7} However, as patient care became more collaborative, so did the use of technology to support management of pain in interdisciplinary care\cite{8} and use of informatics-focused approaches to improve processes of care.\cite{9} As the burden of chronic disease management (CDM) increases worldwide, there is a dire need to address pain in routine care. The field of pediatric medicine is not alone in this regard. Pain is the most distressing aspect of a chronic disease in children and can play a predominant role in their everyday lives.\cite{10} Studies have shown that children who regularly experience pain perceive themselves to be more disabled, are more likely to restrict their activity and their pain related to disease commonly persists into adulthood.\cite{11-13} For example, in a prospective observational study of children with Juvenile Idiopathic Arthritis (JIA), up to 76% of children reported pain on more than 60% of all days \cite{11,14} and almost 40% of children documented pain every day.\cite{14}

Despite the known long term effects of pain on quality of life, the assessment of pain experience in CDM varies. This is especially true in pediatric care\cite{11,15} where studies have shown that assessment of pain experience in children and adolescents largely remains inconsistent.\cite{16-18} A variety of factors including busy clinical workflow or lack of evidence may contribute to a lack of complete and consistent pain experience assessment. However, it could also be that factors influencing overall pain experience may also be difficult to assess routinely, such as the behavioral risks for pain. Studies have shown that many behavioral risks may influence the overall pain experience in children and adolescents.\cite{19-21} These include sleep deprivation, anxiety, depression, and painful conditions affecting a caregiver living in the child’s home.\cite{11,17,22} A child’s pain experience is directly related to the number of family pain conditions, average level of parental pain and number of parental pain conditions.\cite{21} Pain is exacerbated by changes in levels of stress, coping and mood\cite{23} and differences in anxiety levels have shown to predict pain and participation levels in social and school activities\cite{14}. Furthermore, when coping with higher levels of pain, children tend to use less positive self-statements and engage more in overly negative thinking about pain, i.e. catastrophizing statements.\cite{24-26} Thus they are more likely to experience internalizing problems and have an overall poorer quality of life\cite{27}.

Fortunately, many evidence-based behavioral risk screening guidelines exist to implement complete and consistent assessment of pain routinely\cite{28-30}. Therefore, if the many demands and constraints of the clinical workflow, including those with the use of modern electronic medical records (EMR) are met, these guidelines can be deployed in practice at the patient-level using a precision healthcare approach. For example, many commercial EMRs implement pain rating scales\cite{31}, however, very few if any support screening for behavioral risks in a CDM setting. Furthermore, lack of behavioral screening for pain is compounded because most health care systems lack the impetus and the resources to address it in the clinical workflow. Therefore, an informatics based complete and consistent pain assessment implementation outside the EMR may help in this regard.

We have shown in general pediatrics that evidence based screening can be efficiently implemented using an algorithmic approach in a computer-based clinical decision support system (CDSS).\cite{32} Following this suite, we developed an automated screening solution, the Patient Risks Outcomes and Barriers Evaluation (PROBE) tool\cite{33}, to facilitate complete and consistent assessment of pain experience in young children and adolescents at their routine visit in a CDM setting. Although, external to our EMR, PROBE integrates patient’s screening information in the clinical workflow, and gathers evidence for any further evaluation. In this pilot study, we 1) evaluate PROBE for screening behavioral risks for pain in a busy pediatric specialty care workflow; and 2) examine the relationship between self-report of chronic pain (CP), behavioral risks and clinically measured disease activity.
Methods

Patient Risks Outcomes and Barriers Evaluation (PROBE): PROBE as a data capture tool has been described before. [33] It is implemented using the freely available Research Electronic Data Capture (REDCap) database platform [1;34], and commercially available electronic tablet devices (iPad). We added custom logic to deploy PROBE in pediatric rheumatology waiting rooms of our large healthcare system for screening patient’s behavioral risks for CP.

Briefly, the iPad devices connect to the REDCap platform using a clinic-wide secure wireless connection. The web-browser interface on iPad provides for patient input to a screening form. The data corresponding to a form is captured and hosted on a dedicated server for protected health information (PHI). Customized logic ties it all together, for example calculates assessment scores on fields (where applicable) and links the patient screening, nurse and the provider worksheet forms. Please refer to [33] for details of these forms and associated clinical workflow. The latter captures clinical measurement(s) of patient’s chronic disease activity from their EMR and is completed by a study coordinator (for aim 2). Clarifications on this form regarding patient’s disease activity were sought from their attending physician if any. A summary of screening instruments implemented in PROBE is described below.

Behavioral Risks and Pain Rating Scales:
This study focuses on variables that are potentially modifiable for patients with existing clinical resources and treatment options. Therefore, we are using validated screening instruments as listed below. A single yes/no question was used for chronic pain assessment as listed below in (g).

a. Childhood Depression Index and Screen for Child Anxiety Related Emotional Disorders (SCARED); [30]
b. Bedtime problems, Excessive daytime sleepiness, Awakenings during the night, Regularity and duration of Sleep and Snoring (BEARS); [29]
c. Parental Pain History Questionnaire (PPHQ): 12 item yes/no questionnaire directed towards the caregiver for parental pain conditions and if they received any treatment for it e.g. lower back pain, scored [28]
d. Brief pain inventory scales: Numerical ratings to describe pain in the last week on a 0 (no pain) to 10 (pain as bad as you can imagine) scale. [35]
e. Parent or patient reported global assessment (PaGA): “Considering all the ways that arthritis affects you / your child, please rate by selecting a number (in 0.5 increments) that best describes your / child's well-being: from 0 (overall well-being is very well) to 10 (overall well-being is very poor).” (in consultation with pain experts at our institution)
f. Pain Coping Questionnaire: 3 items for measuring self-efficacy on a 5 point scale, scored. [28]
g. Chronic Pain (CP) (self-report): “Have you / your child experienced pain more than 3 days per week for the last 3 months?” (yes/no) is asked of patient / parent to capture CP. (in consultation with pain experts at our institution)

Disease activity measure(s):
The American College of Rheumatology 30 (ACR30) criteria [36] measures patient’s disease activity. To avoid pain as a confounder in ACR30, we use an alternative measure, the Juvenile Arthritis Disease Activity Score or JADAS for patient’s disease activity. JADAS-27 is a multifactorial measure and is responsive to clinically important differences. [37]

Dataset and Clinical Setting:
The PROBE tool was used in three practices of our tertiary care quaternary referral pediatric rheumatology practice. JIA is the most common chronic rheumatologic disease seen in the referral second opinion based practice. The data collected via PROBE are from April 2014 to April 2015 and the analyses are limited to patient visits where data exists for both screening and disease activity measurements during the study period.

Study outcomes of Interest:
Based on self-report of CP (yes or no), patient-visits (first visit for patients with multiple visits) were divided into two groups Study outcome(s) are association of a) presence or absence of self-report of CP; and b) numeric parent-patient global self-assessment score (PaGA). Independent predictors are behavioral risks, pain rating scales and disease activity scores. This study was approved by our Institutional Review Board (IRB). All patient data were de-identified for statistical analyses.

Statistical Methods:
Patients with and without self-report of CP were compared on demographics and diagnosis using Wilcoxon rank sum, Chi-square, and Fisher’s exact tests as appropriate. Visits at which patients reported CP were compared on clinical factors using univariable logistic regression models with generalized estimating equations (GEE) to adjust for the correlation between visits of the same patient. The associations between parent-patient global (self) assessment (PaGA) and pain coping scales were performed using the nonparametric Spearman correlation coefficients.

Models
We developed two prediction models from our dataset: a) to predict self-report of chronic pain; and b) to predict PaGA (self-assessment) score. To assess which demographic and clinical characteristics predict CP (at the visit level), multivariable logistic and linear regression models with GEE were created using backward selection on the following set of potential predictors: age, sex, five anxiety measures, three pain coping measures, five sleep problem measures, uveitis, normalized ESR, active joint count, and limited joint count. JADAS-27 score was used as a potential predictor of CP but not for PaGA (since PaGA is one of the components of the JADAS score). All analyses were performed on a complete-case basis. All tests were two-tailed and performed at a significance level of (p-value) 0.05 using SAS 9.4 software (SAS Inst., Cary, NC).

Results
A total of 148 visits from 109 patients were recorded during the study period. Patients generally visit in 3 month intervals (regular provider or infusion visits), 70% of patients had 1 visit record during the study period. Majority are female, with median age of 13 years. (Table 1)

Chronic Pain, Disease Activity and Pain rating scores:
More than half of the patients (n=56, 51%) self-report CP during their routine visits. (Table 1) For these patients, their disease activity score (JADAS-27) is 4 points higher (or worse) on average (Table 1); and their weekly pain rating scores are 3 points higher (or worse) (Table 2). When comparing CP to no CP group, there are significant differences in self-report of anxiety symptoms, sleep problems, average weekly pain scores, and pain coping skills, active joint count (AJC), physician global assessment (PGA), and parent-patient global assessment (PaGA) (Table 2). For subsequent analyses, we limit to patient’s first visit in our record.
Chronic Pain (CP) Prediction Model
This model includes the following three variables – a pain coping variable (on a 1-5 scale with higher numbers indicating difficulty coping), sleep variable (yes or no), and a variable for Child Separation Anxiety Disorder (measured on the screened sub-scale). The odds of self-report of CP are 2 or more times higher (OR: 2.3, CI: 1.5 – 3.6, p < 0.001) for a unit change in pain coping scale score (to worse, i.e. to a higher score on a scale of 1 to 5). Thus, a 4 point difference in score (between the best and worst pain coping skill score) makes the odds for self-report of CP 8 or more times likely. Similarly, night time awakenings makes the odds 5 or more times likely (OR: 5.5, CI: 2.2 – 13.7, p < 0.001). In contrast a unit increase in measure of disease activity (JADAS-27) only increases the likelihood (of self-report) of CP by 30% (OR: 1.3, CI: 1.1 – 1.4, p < 0.001). The CP model also shows that patients with poorer pain coping skills have 60 – 90% probability of reporting CP when compared to 5 – 25% for patients with better coping skills even after adjusting for their disease activity (Figure 1).

Patient/ Parent Global Assessment (PaGA) Prediction Model:
This model includes the following two variables – one pain coping variable (on a 1-5 scale with higher numbers indicating difficulty coping), and one sleep variable (yes or no). For a unit change to worse (higher) score for patient’s pain coping skill level, the mean change is two units in PaGA score (adjusted mean effect: 2.0, CI: 1.3 – 3.1, p = 0.003). The spearman correlation coefficient between PaGA score and pain coping scale is 0.34 indicating low to moderate correlation. Self-report of patient problems such as falling asleep at bedtime increases the risk of self-report of CP to 3 or more times likely (adjusted mean effect: 3.6, CI: 1.5 – 8.5, p = 0.003). Pain coping skill scores predict measure of self-assessment and over all well-being. Please see Figure 2 details.

Discussion
Previous work has reported 30 - 40% of patients report chronic pain in a chronic condition like JIA. [22; 25] However, these findings are based on population-based sampling approaches, i.e. retrospective analyses of existing data or data outside the clinical visit (e.g. daily diaries). In contrast, our results from screening to implement a complete and consistent assessment of pain (experience) in pediatric specialty care shows that more than half of the patients (children and adolescents with a chronic condition) report chronic pain at routine visits. Additionally, we find that even after accounting for patient’s clinically measured disease activity, report of poorer coping skills (self-assessment of pain coping skills) strongly predicts self-report of chronic pain and this association is even stronger with report of patient’s sleep problems, e.g. night awakenings in adolescents (Figure 1). Furthermore, patient’s pain coping skills...
also largely predict their self-assessment score (for well-being), a well-recognized quality indicator of patient outcomes in CDM settings (Figure 2). Besides these symptoms of separation anxiety in younger children are other significant co-morbidities that associate with self-report of CP in our study. These findings have implications - not only for pain research in near future but also for addressing chronic pain, especially in pediatric subspecialties as also suggested by some other studies. Several studies have suggested that behavioral and cognitive therapies may be useful adjuncts in treatment of chronic conditions such as JIA. [25;38] Our findings corroborate with these previous studies and also add to it – a patient’s coping skill level reflect their overall well-being and thus in turn sheds some light for individualized pain assessment and treatment strategy.

As with all studies, our study also has some strengths and limitations. Behavioral risk assessments implemented in PROBE are applicable to a larger pediatric population. Therefore our findings may be different (perhaps stronger) for another chronic condition and speaks for the generalizability of the approach and the need for implementing care based quality indicators in routine practice. [39] Our limitations include a cross-sectional data analyses of self-report of CP linked to the clinical disease activity measures from patient’s EMR for a given visit, e.g. physician global score and active joint counts. Therefore, it’s possible that patient outcomes (chronic pain report, patient global score) may have improved in subsequent visits. However, we have not studied these outcomes longitudinally and the study is also limited by inherent selection bias - parent and patient perceptions of pain and pain experience may differ. [12] We have also not analyzed this dataset by the person reporting, i.e. parent vs. adolescent. Since the median age of patients in our study is 13 years, we infer that our results are more applicable to adolescent patients. Regardless, our approach makes a case for precision medicine for pain management in practice.

**Conclusion**

There is a dire need to implement screening for behavioral risks for chronic pain in children and adolescents in routine care, particularly in CDM settings. We presented an innovative approach to address individual’s pain predictors in this study. Our findings suggest that enhancing a tool like PROBE into a functional CDSS to support risk identification and stratification for clinical decision making may be highly desirable for driving precision healthcare initiatives.

**Acknowledgements**

Dr. Anand received a grant from the Cleveland Clinic Foundation (CCF) to support this work. The authors wish to thank the following individuals: Susan and Art Karas for their valuable donations; and Sarah Worley and Anne Tang at QHS for providing statistical support. We would also like to thank the staff at the Center for Pediatric Rheumatology at Cleveland clinic for their help and support for this study.

**Ethics Approval:** This study was performed with approval from Cleveland Clinic Institutional Review Board (IRB).

Abstract

Mental health is the largest cost driver of healthcare. ClinicalTrials.gov is a web-based registry of trials conducted in human participants worldwide and serves as an important resource for both practice and research. We use the registry and dynamic topic modeling (DTM) methods to discover hidden topics and their evolution over last 17 years in trials in bipolar disorders. Our model suggests a “priority shift” from drugs to device and among populations studied in mental health trials. For example, transcranial magnetic stimulation for treatment resistant depression (TMS for TRD) trials have increased ($\chi^2 = 52.99$, $p<0.001$, $n=187$) while standardized drug safety and efficacy trials have remained constant ($\chi^2 = 0.72$, $p=0.39$, $n=101$) and more trials focused on pediatric and adolescents ($\chi^2 = 2.98$, $p=0.08$, $n=133$) may have been conducted since FDAAA 2007. We also derive unique data-driven insights in the discovered topic areas in this model based study.

Mood Disorders; Patient Selection; Natural Language Processing

Introduction

Mental health is an important societal issue. About 20% of adults and children are affected by some form of mental disorders in the US [1;2]. Globally, the costs for mental health care are greater than the costs for diabetes, respiratory disorders, and cancer combined and was estimated at $2.5 trillion by 2030 [1;2]. Mental health clinical trials in the past studied safety and efficacy of therapeutic or behavioral interventions in many conditions ranging from schizophrenia to depression. However, it is not clear if there are emerging trends and topics in mental health trials since ClinicalTrials.gov registry was established.

The ClinicalTrials.gov (www.clinicaltrials.gov or registry) is a web-based registry and results database for clinical studies of human participants that was established in 2000. The registry and site are maintained by the National Library of Medicine (NLM) in the US and serves as an important resource for patient families, health care professionals and researchers globally. The FDA Amendments Act of 2007 (FDAAA) made trial registration and reporting of results mandatory and voluntary registration prior to this period enriched the registry database. For example, it might be important to know if past mental health trials addressed conditions like schizophrenia or others such as depression and mania as well and in which populations. It may also be important to know whether these past trials have seen any “priority shift” in terms of treatment options and modalities. Such information may influence current and future guidelines for practice and spur new research directions [4-5]. In fact the Cochrane Collaboration, a volunteer-based organization leverages a volunteer workforce of 37,000 people for publishing systematic reviews for such purposes [6].

By analyzing word co-occurrence patterns, topic models can discover underlying themes or “topics” from collections of documents [7]. They use statistical algorithms to discover underlying themes, for example “political”, “sports” and “current affairs” from news articles. In this study, using dynamic topic modeling (DTM) methods [8], we analyze trial records related to “mania” and “bipolar disorders” in the registry - to discover topics from the last 17 years. Furthermore, we analyze topic trends over this time and trial characteristics such as sponsors, and participants associated with them.

Methods

A search using the keywords “Mania OR Bipolar Disorder” was initiated from the registry site on Nov. 24, 2016. The search resulted in 1220 trial records ranging from 1999 to 2016 and these were downloaded to a CSV file for further analyses. The details of variables comprising a trial record in the registry are given in Table 1. We used the “Title” and “First Received” variable fields in each record as inputs to learn a statistical model (please see Dynamic Topic Model section below) of word co-occurrence patterns that evolve over time. From this learned model, useful insights such as likely sponsors of a study area (topic), interventions studied and participant characteristics are derived, by analyzing individual documents (trial records) that meet certain threshold criteria.

Dynamic Topic Model

Topic models are generative latent variable models. They assume that the observed data is produced by a generative process, which is governed by hidden random variables. Thus the generative process defines a joint probability distribution over the observed and hidden random variables. The aim of the model is to learn conditional probability distributions or
A classic example of a topic model is Latent Dirichlet Allocation (LDA). LDA formally defines a “topic” as a distribution over a fixed vocabulary of words in a document collection. The observed variables in the model are the words in each document. LDA assumes that a document corpus expresses a set of K topics, where K is empirically chosen. Words in a document are then generated as such: a word in a document is drawn from one of the K topics, where the selected topic (topic assignment for the word) is chosen according to a per-document distribution over topics. The goal then is to automatically discover the hidden structure of the model, i.e. “topics”, per document topic distribution, and per document per word topic assignment in the collection. In a LDA model each document exhibits all K topics, but in different proportions.

The inference problem is to learn the hidden structure given the observed words in the collection. LDA makes certain assumptions, first, the number of topics to be discovered are known, second, the ordering of words (“bag of words”) in the documents or for that matter ordering of documents in the collection does not matter. However, for large corpora that run over years, such as from the registry, this assumption is not appropriate. Modeling the temporal order of documents in these collections is important for understanding topic evolution over time. Therefore, one approach is to use dynamic topic modeling methods (DTM) [8]. In DTM methods a “topic” is defined as a sequence of distributions over words rather than a single distribution of words. Thus, if a collection is arranged by years, each year is a “time slice” in DTM and documents with in each slice form a component topic model (e.g. LDA). This change facilitates tracking of thematic change in a collection over time or topic evolution and approximate structured variational inference techniques are used to infer an approximation to the posterior [9].

Model Selection and Introspection

We apply DTM to the “Title” and “First Received” fields in the downloaded dataset. Typically to learn a probabilistic model from the collection or “corpus”, a desired number of discoverable topics (empirically chosen or derived using other statistical techniques) along with initial parameters are given to the algorithm. We empirically chose to discover 8 topics from a corpus of 1220 trial records spanning over 17 years. We used an open source Natural Language Tool Kit (NLTK, www.nltk.org), and free python library for topic modeling http://pydoc.net/Python/gensim/0.11.1/gensim.models.wrapper_s.dtmmodel/). NLTK was used to build the dictionary and corpus from the document collection and Gensim wrapper to set model parameters for learning the DTM. The learned model gives probability mass in document-topic matrix from which we calculated a) mean topic proportion per year or topic evolution over time (in years); and b) number of documents per topic by year. We used a $\chi^2$ test to evaluate if the aggregate of mean topic proportions for a given topic before and after 2007 (FDAAA mandatory trial registration) has changed. By further analyzing individual documents (trial records) that meet a high threshold for a “given” topic (e.g. 0.9 in the document-topic matrix) we derived other useful insights. The threshold was chosen empirically and the results are described under the heading “Insights” in Results section. Among trial records expressing topics with the high-threshold probability we analyzed records for gender, recruitment status and study phase (based on 80th percentile cutoff).

Results

Our final model discovered 8 topics from the “Title” field in the registry records which were divided amongst 17 time slices based on the “First Received” study variable.

Topic Proportions and Evolution

Figure 1 describes the topic proportion and evolution over 17 years of registered trials. The topics are labeled T0 to T7 with human interpretation in Table 2 (by physician author – AA).

Mean topic proportion for every time slice is plotted in Figure 1a. As can be seen the document topic proportion varies over time which describes its evolutionary path. Such a variation would be expected in most topics due to changes in research focus, funding priorities or policy changes. Figure 1b describes the number of trials by topic in each year. As can be seen from here a large proportion of mental health trials were registered in 2005. This may correspond to the international committee of medical journal editors (ICJME) guidance of 2004, i.e. to require trial registration in consideration for publication. However, for some topics these variations are more pronounced, please refer to Table 3 for statistical results.

For example, topic T7 (transcranial magnetic stimulation for treatment resistant depression or TMS for TRD) trials form a larger proportion of mania and bipolar disorder trials since 2007 (Figures 1a and b). Since 2007, severe pediatric depression risk studies (T0) may have gained focus perhaps reflecting a health priority and the topic of “placebo controlled trials” in two drug standard treatment options lithium vs. lamotrigine (T3) for depression, has been relatively constant.

Insights

The following insights are derived from trial records exhibit ing topic with high-threshold probability. Bolded headings indicate the variable field used for these analyses.
Study Types: The registry consists mostly of “interventional” trials, but there are some “observational” trials such as pediatric depression risk, acute psychosis, alcohol dependence, and cognitive therapy in children and adults (T0, T2, T4, T5, and T6 respectively).

Gender: Most mental health trials are conducted in both female and male genders, however, among Quetiapine (brand name Seroquel) treatment effect trials (T4), 20% are in males. Similarly, among trials studying cognitive therapy for weight (T6), 15% are in females only. (Figure 2)

Study Phase: Of note here, transcranial magnetic stimulation trials for treatment resistant depression are being conducted in all study phases. Cognitive behavioral therapy trials (T6) are in Phase 1, exception being trials in children and adolescents (T5), some of which are also in Phase 1|2 or Phase 4.

Recruitment Status: All placebo controlled drug trials for lithium vs. lamotrigine (T3) have been completed. About 85% of cognitive trials in adults (T6), and 90% of Olanzapine trials (T1) and acute psychosis treatment and symptoms trials (T2) have been completed. On the other hand, only about 50% of trials in children for severe risk of depression (T1) or cognitive therapy for anxiety (T5) have been completed. Trials of TMS for TRD are still recruiting and more than half of them have been completed.

Study Designs: Most trials are “Randomized” interventions. Some are “Observational” and these mostly study safety and efficacy (T0, T1, T2, T3). Other design parameters include case or cohort-control design (T1, T4, T6), group (T5), parallel crossover, double blind, open and non-open-label.

* Significant at p=0.05
Eli Lilly, the pharmaceutical and Massachusetts General Hospital (MGH) stands out in pediatric depression risk trials (T0) sponsored by the National Institute of Mental Health (NIMH). AstraZeneca, Merck and other pharmaceuticals stand out in Olanzapine safety and efficacy trials (T1) and Stanley Medical Research Institute for acute psychosis related trials (T2) sponsored by NIMH. Roxane and GlaxoSmithKline dominates placebo controlled lithium vs. lamotrigine trials (T3). NIMH also sponsors many of the alcohol dependence trials (T4), cognitive therapy trials (T5, T6) at MGH, Dartmouth Hitchkock, VA Palo Alto in the US. A larger proportion of TMS trials for TRD (T7) are done in “Research Universities” sponsored by NIMH, besides these there are trials in Denmark, Norway as well.

Experimental Interventions: Please refer to Figure 4. Compound LY2216684 and Ketamine may be studied in severe pediatric depression risk trials (T0) along with family focused cognitive therapy and mindfulness. Aripiprazole, Lithium, and Depakote may be studied in safety and efficacy trials (T1). Tamoxifen is being studied in acute psychosis trials (T2). Behavioral interventions, and drugs Topiramate, Aripiprazole may be studied in depression trials (T3).

Compound AZD6765 and Naltrexone may be studied in alcohol dependence trials (T4). Ziprasidone along with Risperidone and Behavioral therapy may be studied in cognitive therapy trials for anxiety in children and adolescents. (T5) Mindfulness, Psychoeducation along with Cognitive therapy may also be studied in adults (T6) and Transcranial Magnetic Stimulation (TMS) is being studied for treatment resistant depression (T7) and most drug trials are placebo controlled.

Figure 4 - Interventions studied in topics (size of words reflects the frequency in each topic, Left-Right: T0 to T7)

Discussion

We discovered thematic areas or topics in mental health trials using DTM. Analyses of these topics provide unique insights into the hidden characteristics of the registry corpus. However, our study has some limitations. First, we selected 8 topics to discover empirically. It is possible that with a different number of topics, the model may produce finer or coarser thematic areas. An alternative approach to address the issue is to use a purely data-driven approach for number of topics such as the hierarchical Dirichlet process [9]. However, the chosen model is a good start for further improvement and the insights are from the “unknown”. From the results, TRD using TMS trials started in larger numbers since 2007. This may be due to the commercial availability of TMS and its FDA approval in 2006. Trials of safety and efficacy with older drugs such as Standard treatment drug trials for depression show a downward trend [10-14]. Severe pediatric depression risk trials have gained focus in recent years [15-20] and cognitive therapy as an intervention is being studied even in the pediatric population perhaps reflecting a health priority. Additionally, newer compounds such as LY2216684 [21] and AZD6765 [22-24] are currently studied although they may be experimental in
nature. These findings can be used to drive resources for research in a precision healthcare system.

**Conclusion**

Insights from a text model based analyses of ClinicalTrials.gov registry reflects trend in the field of mental health trials, particularly in bipolar disorders. Our findings suggest that there may be a “priority shift” - from drugs to device based (TMS) intervention and to study adult as well as children and adolescent population in clinical trials in recent years. This may be due to several reasons for example, availability of newer technologies, and due to high-level policies such as national health priorities and push towards precision healthcare driven systems.

MedEx/J: A One-Scan Simple and Fast NLP Tool for Japanese Clinical Texts

Eiji Aramaki, Ken Yano*, Shoko Wakamiya

Nara Institute of Science and Technology (NAIST), Japan

* Contributed equally to this work.

Abstract

Because of recent replacement of physical documents with electronic medical records (EMR), the importance of information processing in the medical field has increased. In light of this trend, we have been developing MedEx/J, which retrieves important Japanese language information from medical reports. MedEx/J executes two tasks simultaneously: (1) term extraction, and (2) positive and negative event classification. We designate this approach as a one-scan approach, providing simplicity of systems and reasonable accuracy. MedEx/J performance on the two tasks is described herein: (1) term extraction ($F_{\beta=1} = 0.87$) and (2) positive–negative classification ($F_{\beta=1} = 0.63$). This paper also presents discussion and explains remaining issues in the medical natural language processing field.

Keywords:

Medical Informatics; Natural Language Processing

Introduction

Medical reports using electronic media are now replacing those of paper media. Correspondingly, information processing techniques in the medical field have radically increased their importance. Especially, natural language processing of numerous medical reports and obtaining knowledge from them has drawn much attention for its promise of facilitating precise and timely treatments [1].

Our goal is to promote the development of practical tools that support medical decisions. For medical reports in English, several tools have become available, such as the MAYO Clinic Vocabulary Server, MedLEE [2], and CTAKEs [3]. In contrast, tools for Japanese texts are not yet available. Considering that most clinical text is written in the respective domestic languages of users, it is reasonable to develop language-specific processing tools for each language.

To process Japanese texts, this paper presents a proposal of a Japanese clinical NLP tool, designated as MedEx/J, having the following two functions.

1. **Entity Recognition**: This task identifies expressions of diseases and complaints in clinical texts. This task is similar to a named entity recognition task. Herein we name this task ER.

2. **Positive–Negative (P/N) Classification**: Because clinical texts include various events, not only the current disease (**positive disease**) but also earlier diseases and suspected diseases, events do not always occur. We regard such an entity that does not occur in a target patient as a **negative entity**. We designate the task of classification of a positive entity and negative entity as P/N Classification.

These workflows are presented in Figure 1. The respective tasks are important for medical NLP. For example, an Automatic Content Extraction (ACE) information extraction program deals with event extraction, by which each event is annotated with temporal and modal markers. A similar effort was made in Time relation (TimeML) [4] and the Penn Discourse TreeBank (PDTB) [5] projects (discourse relation). Usually, a state-of-the-art extraction method is based on Conditional Random Fields (CRFs) [6].

The P/N classification presents an important issue because negative events are frequently described in clinical texts. Negative events have two characteristics. First, various words (or sometimes phrases) affect the negation of events. Another is that a word that triggers a negation sometimes has a long scope. Because of the observation presented above, a heuristic approach suffers from its handling of various negative patterns, thereby motivating the use of machine learning methods for negative detection [7-9].

Compared to these earlier works, our method has two important differences that are readily apparent: (1) character-based processing, and (2) the fusion of two tasks (both entity recognition and P/N classification).

- **Character-based NLP**: Traditional NLP studies regard a word as a minimum unit. A clinical text, however, includes numerous complex nouns consisting of multiple Chinese characters. This complexity often leads to errors of morphological analyses. Therefore, this study uses a character-based method with no preprocessed.

- **Fusion task**: Usually, the P/N classification task is applied after the first entity recognition step. However, we combine these two tasks into one because we consider that the required information for P/N classification resembles that of the entity recognition.

In addition to the benefits described above, these two features dramatically simplify the system. One system can be built with no extra systems. In compensation for the system simplicity, the

Figure 1 - Workflow of MedEx/J.
task must solve a complex task, term identification with P/N classification, which invariably produces large feature spaces. We designate this approach as a one scan approach because multiple tasks are solved under one sequential labeling.

The experimentally obtained results reveal that, in spite of the risk of large feature space caused by our one-shot approach, our method has achieved high performance, (1) term extraction ($F_{beta} = 0.87$) and (2) positive negative classification ($F_{beta} = 0.63$), demonstrating the feasibility of the proposed approach.

**Materials: The NTCIR Clinical Text Dataset**

To implement the proposed method, we use a corpus consisting of the NTCIR shared task data [10] and its compatible inline dataset. In these data, the symptom and diagnosis related expressions are marked with $<p>$ (for a positive entity) or $<n>$ (for a negative entity) as follows.

- **Compound noun:** noun compound word was marked as a whole.
- **Verbal phrase:** verbal phrases were not marked.
- **Disease identification test:** the disease was marked if and only if the existence of the certain virus represents a single particular disease.
- **General description:** when the expression describes ‘general’ information related to the disease and/or the name of the clinic, it was not marked.
- **Non-alphabetical character:** non-alphabetical characters and non-numerical characters (e.g., “|” ) were marked with the prior noun phrases if and only if the marks represented the conditions and were attached to the previous noun phrases to form the names of the disease.
- **Modality related word:** Words and phrases that suggest modalities of the symptoms (e.g, positive 陽性, negative 陰性, prevention 防予防) were not included in tags. However, some modality-related words were included if and only if they were connected to compose the standard disease names.

For detailed information related to the annotation scheme, see the annotation guideline available on the web[13]. We used data consisting of 468 (9,286 sentences in total) Japanese documents.

**Methods**

**Character-based labeling**

Using the corpora described in the material section, we adjusted the proposed NLP tool. In our task scheme, an input is a sentence. The output is a sentence with $<p>$ (for positive) or $<n>$ (for negative). This output represents two tasks: (1) entity recognition and (2) P/N classification. The first task is represented as the tagged scope. The second task is represented as the type of tag ($<p>$ or $<n>$).

The ER is to mark the beginning (b), the inside (i), and the outside (O) labels over input text sequences. Differences between the proposed method (character-based) and the existing method (word-based) sequence labeling are explained below (Fig. 2).

![Figure 2 - Sentence representation in sequential labeling](image)

**Fusion Method: ER with P/N classification**

The P/N classification is usually applied to the ER results. In contrast, we propose a one-shot approach to solving these two problems simultaneously by handling positive and negative events as independent negative entities.
Negative events are associated with negative or suspicious predicate phrases, emerged in generic or unrelated context with patients. For negative entities, we use ‘B-N’ and ‘I-N’ labels, respectively, instead of ‘B-P’ and ‘I-P’. Following are some samples of negative predicate phrases that frequently emerged in our corpus.

- \(<\text{N}>\)恶性腫瘤(\(<\text{N}>)\)を感知された
- \(<\text{N}>\)発熱(\(<\text{N}>)\)は認めなかった
- \(<\text{N}>\)肺結核(\(<\text{N}>)\)は否定的だった

It is noteworthy that only the negative entity is annotated. Negative trigger phrases, such as “suspicious of” and “not found”, are captured explicitly by machine learning.

Results

Corpus and Setting

For evaluation, we collected another set of 500 (10,266 sentences in total) annotated Japanese discharge summaries, which were not used to construct the model for CRF. We used the CRF toolkit with standard parameters\cite{Lafferty}. We then investigated the feature contribution to the performance in learning settings of two types: word-based and character-based. To compare the performance against a word-based method, we implemented both methods.

Evaluation metrics

Performance of the first task (ER) was assessed using the precision, recall, and F-measure ($\beta=1$) according to earlier studies. Precision is the percentage of correct entities found by a participant’s system. Recall is the percentage of entities present in the corpus that were found by the system. The $F$-measure is the harmonic mean of precision and recall. An entity is regarded as correct only if it was an exact match of the corresponding entity in the data file. The evaluation method is the same as that used for the CoNLL-2000 shared task. A Perl script used for evaluation is available at the CoNLL-2000 website\cite{Kamps}.

We adopted evaluations of two types. ER (only) and ER+P/N classification (fusion task). ER was a complaint and diagnosis or not: only entity. Modality included modalities of two types: positive or negative.

Table 1 presents performance information of the ER task associated with character-based method and word-based method. The proposed character-based method outperformed word-based method in all three metrics. Table 2 presents performance of the fusion method: ER + P/N classification. In this task, the character-based method also outperformed the word-based method in all metrics. The N-tag performance was not good compared with that of P-tag, suggesting that P/N classification is a rather difficult task. This observation is reasonable because P/N classification sometimes becomes a difficult decision during annotation by humans.

Figure 4 - Performance and the corpus size.

Discussion

Next, several remaining issues are investigated: the corpus size effect, entity coverage, and processing time.

Corpus size effect

It is important to ascertain how many data are required for training. To investigate this point, the performance of character-based methods for the fusion ER task was analyzed by changing the corpus size from 10% to 100% in 10% steps. Figure 4(a) presents the performance change of \(<p>-tag extraction. Figure 4(b) shows that of \(<n>-tag extraction. The performance of each increases gradually as the corpus size increases. The recall rate tends to be more affected by the corpus size than by the precision rate. From these figures, we inferred that the performance did not reach a plateau even when using the entire corpus, therefore suggesting that some room exists for improvement by increasing the corpus size.
Entity coverage: Instance level analysis

Figure 5 presents the type or token coverage of the top $n$ frequent terms. The figure shows a typical long-tail shape in which the top 500 terms occupy only 50% of tokens, which implies that many varieties of terms appear in the clinical texts, also motivating the corpus increase.

Processing Time

Performance and processing speed are important indicators for practical systems. In our estimation, a large hospital such as a university hospital handles 3,000 patients daily, generating 60,000 sentences per day. We checked the CPU time of a processor (core i7 6800K 6core/12thread 3.4 GHz (Turbo Boost 3.6 GHz)) and its associated memory (32GB (8GB=4) DDR4-2133 Quad-Channel). The time to process 1,000 sentences was 2 min 44 s for training and 2 s for tests, which indicates that 120 ($=2\times60,000/1000$) s is sufficient for all patients in one day. We regard this as a practically feasible time for most hospitals.

Future task

An important problem persists: mapping the extracted term to the concept, such as ICD-10 or SNOMED-CT [12]. We are also trying to develop this module incorporating the orthographic disambiguation techniques. Another remaining task is to use a smarter method such as Recurrent Neural Network (RNN). However, we think our one-scan approach presents certain benefits in terms of system simplicity.

![Figure 5 - Coverage ratio of top 25–10,000 frequent token (red) or types (white) of entities. Coverage ratio is calculated as follows: Coverage ratio = (accumulated frequency of top n types or tokens) / (total frequency of all types or token is the training corpus)](image)

In summary, room for improvement remains, requiring more novel approaches, error analyses, and more effort for this task to meet its needs.

Conclusions

We developed a Japanese clinical tool, MedEx/J, consisting of two functions: (1) term extraction and (2) P/N classification. Our approach executes both tasks as one sequential labeling. This approach has two important benefits: 1) Preprocessing was simplified because morphological analysis was not required, 2) its performance was much better (term extraction ($F_{p=1}=0.87$) and positive negative classification ($F_{p=1}=0.63$)) than that of a word-based method although using a much simpler feature set for the CRF.

Our results suggest that the approach is extremely effective for handling medical reports. Additionally, we believe that this simple implementation promises great benefits from a practical viewpoint, such as convenience of installation into hospitals, maintenance costs, and the development of commodity applications.

The software is available at [http://sociocom.jp/parser.html](http://sociocom.jp/parser.html).

Abstract
One of the major features required by automated software tools of screening for diabetic retinopathy is the detection of red lesions. This paper presents a new automatic method in order to locate red lesions in color eye fundus images. The method relies on mathematical morphology operators and has a coarse and a fine detection stages, respectively. The former detection stage detects structures of low-intensity values in the retina, such as microaneurysms, hemorrhages, blood vessels and the fovea center. Additionally, the latter stage proposes to improve the detection of red lesions identified in the previous stage. For experiments, we use the well-known publicly available DIARETDB1 database. The results indicate that our method detected red lesions with 75.81% and 93.48% of mean sensitivity and mean specificity, respectively.

Keywords:
Diabetic Retinopathy; Retina; Microaneurysm

Introduction
Evaluation of the retina can provide information regarding the presence of ocular diseases such as glaucoma and macular degeneration. Moreover, chronic systemic diseases such as high blood pressure and diabetes can also be detected through of the retina conditions [1]. Furthermore, diabetes contributes to decrease the health-related quality of life among patients [2]. One consequence of diabetes is vision impairment, or even total vision loss (i.e., blindness). Diabetic Retinopathy (DR) consist in a complication caused by diabetes, and may damage the visual acuity of people at working age [3]. The clinical signs that characterize the Diabetic Retinopathy are the presence of microaneurysms and hemorrhages (i.e., red lesions) that are observable by digital eye fundus photography. Thus, the early detection of red lesions can prevent or delay visual acuity loss in patients with Diabetic Retinopathy.

The main retinal features and red lesions (e.g. microaneurysms and hemorrhages) are illustrated in Figure 1 for a typical retinal image. However, the automatic detection of red lesions is still difficult for several reasons, namely:

1. the red lesions have different sizes and shapes [1];
2. it is difficult to distinguish red lesions from other retinal structures such as blood vessels and the fovea region [4, 5];
3. there are slow background variations and illumination artifacts in the fundus image which contributes to decreases the accuracy of detection of red lesions. Red lesions are quite difficult to detect manually as well, even for an expert in ophthalmology [6, 7].

![Figure 1 - Retinal main physiological structures and lesions in a typical digital eye fundus photo.](image_url)
(i.e., 59.55% of images) containing red lesions (e.g., microaneurysms and hemorrhages).

First, an adaptive contrast enhancement technique is applied to the green channel of the original DIARETDB1 color eye fundus image (e.g., Figure 2(a)). In this stage, we apply the Contrast Limited Adaptive Histogram Equalization (CLAHE) transform to achieve our enhancement results [9, 10]. In this way, a new image \( f_1 \) is obtained as detailed in Equation 1:

\[
f_1 = \text{CLAHE}(f_g),
\]

In our experiments, we have used 10x10 blocks with a normalized clip limit of 0.2 for CLAHE. The \( f_1 \) image is illustrated in Figure 2(b).

Now, on the \( f_1 \) image, we apply the method proposed by Walter et al. [11] to remove slow background variations, and to improve the contrast. This technique uses alternating sequential filters based on morphological closings, \( \phi \), and morphological openings, \( \gamma \), so as to estimate the background \( f_2 \) of the image \( f_1 \), as shown in Equation 2. The morphological opening, \( \gamma(B) = \delta(B) \) \([\delta(B)(f_1)]\), of the image \( f_1 \) is the consequence of the erosion \( \varepsilon \) of \( f_1 \) by a defined structuring element \( B \), followed by the dilation \( \delta \) of the result of the erosion \( \varepsilon \) of \( f_1 \) by the same structuring element. Conversely, \( \phi(B) = \varepsilon(B)[\delta(B)(f_1)] \) is the morphological closing of the image \( f_1 \) (i.e., consequence of a dilation, \( \delta \), followed by an erosion, \( \varepsilon \), of \( f_1 \) by a defined structuring element \( B \)) [12].

\[
f_2 = ((f_1 \phi B \gamma B) \cdots \phi nB) \gamma nB, \tag{2}
\]

where \( B \) is a flat disc-shaped structuring element with a fixed radius of 8 pixels, and \( n \) is the number of iterations (\( n = 2 \) in our experiments) on which the sequential combination of opening and closing is applied. As next step, the image difference between \( f_2 \) and \( f_1 \) is computed. Then, a new image \( f_3 \) without slow background variations is obtained, as detailed in Equation 3. Figure 2(c) depicts the image \( f_3 \).

\[
f_3 = f_2 - f_1, \tag{3}
\]

Additionally, we can identify low intensity regions (e.g., dark areas that potentially are associated with red lesions) using the grayscale reconstruction by dilation as shown in Equation 4

\[
f_4 = \mathcal{R}_{f_1}(\delta^{(n)}(f_1)), \tag{4}
\]

where \( f_1 \) and \( \varepsilon(B)(f_1) \) are the mask and marker images, respectively. In addition a flat disc-shaped structuring element with a fixed radius of 10 pixels was used in the marker image. Figure 2(d) depicts the image \( f_4 \) obtained from the aforementioned described operator.

Afterwards, in order to flatten more the areas related to red lesions, we remove large intensity peaks by applying a grayscale reconstruction by erosion, \( \mathcal{R}^\ast \), as shown in Equation 5. Then, taking \( \delta(B)(f_4) \) as a marker image, and \( f_1 \) as a mask image, the reconstructed \( f_5 \) image is obtained, as shown in Figure 2(e).

\[
f_5 = \mathcal{R}_{f_1}^\ast(\delta(B)(f_4)), \tag{5}
\]

Soon after, the image difference between \( f_5 \) and image \( f_1 \) is computed, as shown below:

\[
f_6 = f_5 - f_1. \tag{6}
\]

The output \( f_6 \) is an image where structures like thin vessels, large vessels, hemorrhage, and microaneurysms are enhanced against the background of the color eye fundus images. Figure 2(f) depicts the image \( f_6 \).

At this point, the difference between the H-minima and the H-maxima transforms of \( f_6 \) (i.e., \( \text{Hmin}_1(f_6) \) and \( \text{Hmax}_1(f_6) \), respectively) are computed according to Equation 7. The image resulting from the difference between \( \text{Hmin}_1(f_6) \) and \( \text{Hmax}_1(f_6) \), namely \( f_7 \), is illustrated in Figure 2(g).

\[
f_6 = \mathcal{R}_{f_1}(\delta^{(n)}(f_1)), \tag{4}
\]

where \( f_1 \) and \( \varepsilon(B)(f_1) \) are the mask and marker images, respectively. In addition a flat disc-shaped structuring element with a fixed radius of 10 pixels was used in the marker image. Figure 2(d) depicts the image \( f_4 \) obtained from the aforementioned described operator.

Afterwards, in order to flatten more the areas related to red lesions, we remove large intensity peaks by applying a grayscale reconstruction by erosion, \( \mathcal{R}^\ast \), as shown in Equation 5. Then, taking \( \delta(B)(f_4) \) as a marker image, and \( f_1 \) as a mask image, the reconstructed \( f_5 \) image is obtained, as shown in Figure 2(e).

\[
f_5 = \mathcal{R}_{f_1}(\delta^{(n)}(f_1)), \tag{5}
\]

Soon after, the image difference between \( f_5 \) and image \( f_1 \) is computed, as shown below:

\[
f_6 = f_5 - f_1. \tag{6}
\]

The output \( f_6 \) is an image where structures like thin vessels, large vessels, hemorrhage, and microaneurysms are enhanced against the background of the color eye fundus images. Figure 2(f) depicts the image \( f_6 \).

At this point, the difference between the H-minima and the H-maxima transforms of \( f_6 \) (i.e., \( \text{Hmin}_1(f_6) \) and \( \text{Hmax}_1(f_6) \), respectively) are computed according to Equation 7. The image resulting from the difference between \( \text{Hmin}_1(f_6) \) and \( \text{Hmax}_1(f_6) \), namely \( f_7 \), is illustrated in Figure 2(g).
The H-minima transform removes all connected basins with grayscale heights (i.e., contrast) less than h. Thus, the output of the H-minima transform is an image where structures like thin or large vessels and hemorrhage are removed. Conversely, the H-maxima transform removes all connected peaks with contrast less than h, resulting in an H-maxima image usually containing only a few basin structures corresponding to peaks higher than h. Thus, subtracting the H-minima from the H-maxima increases the contrast of vessels and red lesions (that usually show low contrast). This processing stage will be important later so as to detect the red lesions without using thresholding techniques.

\[
f_I = \left( H_{\min} f_6 - H_{\max} f_6 \right)^c, \tag{7}
\]

where, H-minima and H-maxima transforms removes the connected basins and peaks. Afterwards, in order to flatten more the red lesions region, we remove large intensity basins and peaks by applying a grayscale closing, \( \gamma \), and a grayscale opening, \( \gamma \), respectively (see Equation 8). Figure 2(h) depicts the resulting image \( f_8 \).

\[
f_8 = \gamma (B) \left( \delta (B) f_I \right), \tag{8}
\]

To improve the red lesions detection accuracy, we apply the toggle morphological contrast enhancement method to image \( f_8 \) [12]. As described by Equation 9, this method uses a grayscale erosion and a grayscale dilation operation.

\[
f_{9|n|a} = \left\{ \begin{align*}
\delta (B) f_8 & \text{ if } f_9(x,y) - \delta (B) f_8 \geq \delta (B) f_8 - f_9(x,y), \\
\delta (B) f_8 & \text{ if } f_9(x,y) - \delta (B) f_8 < \delta (B) f_8 - f_9(x,y)
\end{align*} \right. \tag{9}
\]

where, B is a diamond-shaped structuring element with a fixed radius of 3 pixels.

Finally, in order to detect the red lesions candidate regions we employed the RMAX operator (i.e., which detects the regional maxima pixels) [13]. The regional maxima, RMAX, returns a binary image from the \( f_9 \) grayscale image. If a set of connected pixels of \( f_9 \), namely \( S(\theta) \), have a constant intensity value bigger to its neighboring pixels, then the logical value “1” is assigned to such set of pixels. Otherwise it is assigned zero to this set of pixels. The RM AX image can be found according the Equation 10.

\[
f_{10} = \text{RMAX} (f_9) = f_9 + 1 - R_{\Phi + 1} (f_9). \tag{10}
\]

In order to identify and remove the red lesions regions which are actually regions of the vessel, the circularity of the shape of the regions is calculated. The central idea is that the regions belonging to the network of vessels have an elongated shape, and therefore low circularity. Thus, among the n boundary shapes, we select that one with the highest compactness as described by Equation 11.

\[
f_{11} = \left\{ \begin{align*}
\text{maintain region,} & \quad \text{if } 4\pi P^2 - A \\
\text{remove region,} & \quad \text{Otherwise,}
\end{align*} \right. \tag{11}
\]

where P is the boundary shape perimeter, A the shape area and \( \lambda \) is the threshold used to remove undesirable elongated shapes.

Next, we describe the next stage used for improving the accuracy of the red lesions boundary detection, based on the foreground pixels of the binary image \( f_{11} \). A marker image \( f_{12} \) is obtained according to Equation 12, based on images \( f_{11} \) and on the resulting image from the union between image \( f_3 \) and \( f_6 \). This marker image \( f_{11} \) is illustrated in Figure 3(b).

\[
f_{12}(x,y) = \left\{ \begin{align*}
0, & \quad \text{if } \delta (B) f_1 (x,y) = 1 \\
f_6(x,y) \cup f_6(x,y), & \quad \text{Otherwise,}
\end{align*} \right. \tag{12}
\]

where B is a diamond-shaped structuring element. A dilation using this large structuring element guarantees that the red lesion region is included in \( f_{12} \). Then, using \( f_{12} \) as a marker image and \( f_3(x,y) \lor f_6(x,y) \) as a mask image, the reconstructed image \( f_{13} \) is obtained, as described in Equation 13 and illustrated in Figure 3(c). Hence, only regions outside of the red lesions are reconstructed.

\[
f_{13} = \delta_B (f_3(x,y)) f_6(x,y) / f_{12}. \tag{13}
\]

Figure 3 – Fine red lesions detection. (a) Result after the identification and removal of the vessel network (image \( f_{11} \). (b) Marker image \( f_{12} \). (c) Reconstructed image \( f_{13} \). (d) \( f_{14} \) image. (e) Resulting image \( f_{18} \) containing the final red lesions detected. (f) Binary image \( f_{18} \) without the macula region in the foreground.

Then, the red lesions region is enhanced by subtracting the previously reconstructed image \( f_{13} \) from \( f_3(x,y) \lor f_6(x,y) \) (see Eq. 14), and the result \( f_{14} \) is illustrated in Fig. 3(d).

\[
f_{14} = f_3(x,y) \lor f_6(x,y) - f_{13}. \tag{14}
\]

Finally, in order to detect the final red lesions we apply again the steps shown by equation 7, 8, 9 and 10 in that
order, on the image $f_{14}$. In other words, we obtain four new images namely: 1) $f_{15}$; 2) $f_{16}$; 3) $f_{17}$; and 4) $f_{18}$ (i.e., Fig. 3(e)). Afterwards, as post-processing stage we identified and removed the macula from image $f_{18}$ [19]. The macula is the darker region of the image, and is located near to the optic disk center. Then, as the macula is a region of low intensity, it can be confused with the red lesions. Thus, the remotion of the fovea region provides more precision for detecting the red lesions. Figure 3(f) depicts the resulting image $f_{18}$.

Figure 4 illustrates the methods used in coarse detection stage. Figure 5 illustrates the summarized steps used to improve the detection of red lesions.

**Results and Discussion**

We evaluate the performance of the proposed method using metrics as follows: the measurements of sensitivity, specificity, positive predictive value and misclassified proportion measures [15, 16] on 89 DIARETDB1 fundus images. The sensitivity is given by the proportion of true positives, TP, with respect to proportion of false negative, FN, pixels (i.e., $TN/(TN+FP)$). The specificity is the proportion of true negative, TN, pixels with respect to the proportion of false positive, FP, pixels (i.e., $FP/(TP+FP)$). The predictive value is the proportion of true positives, TP, with respect to proportion of false positive, FP, pixels (i.e., $TP/(TP+FP)$). As indicated in Table 1, the proposed method achieved 75.81% of average sensitivity, and 93.48% of average specificity considering all 53 images with red lesions in the DIARETDB1 database. For the sake of comparison, Table 1 summarizes the red lesions detection results achieved by our method in the coarse and fine stage, indicating that in the fine stage the method significantly improves the results achieved in the coarse stage. It shall be observed in Table 1 that our method also was tested on retinal images not containing red lesions, achieving an average specificity of 94.65% and an average misclassified proportion of 5.35%.

**Table 1 – Performance comparison between coarse and fine red lesions detection (DIARETDB1 database)**

<table>
<thead>
<tr>
<th>Detection Stage</th>
<th>Retinal Images with Red Lesions $^a$</th>
<th>Retinal Images without Red Lesions $^b$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Average sensitivity</td>
<td>Average specificity</td>
<td>Average predictive value</td>
</tr>
<tr>
<td>-----------------</td>
<td>----------------------</td>
<td>------------------------</td>
</tr>
<tr>
<td>Coarse</td>
<td>64.60%</td>
<td>93.28%</td>
</tr>
<tr>
<td>Fine</td>
<td>75.81%</td>
<td>93.81%</td>
</tr>
</tbody>
</table>

$^a$ Comprises 53 images of the DIARETDB1 database.

$^b$ Comprises 36 images of the DIARETDB1 database. The sensitivity and predictive value cannot be calculated because all TP (True Positives) and FN (False Negatives) values in color eye fundus images without red lesions are equal to zero.

The method proposed in this work is based on mathematical morphology and it presents important features. Initially, the method relies on adaptive morphological operators, as the operator of maximum regionals. It is applied to two stages of red lesion detection, namely, preliminary detection and refined detection, adapting according to the processed image. Hence, basic threshold is discarded in our method because it does not take into consideration image peculiarities. Another remark regarding the method is its robustness. The method presented in this work is not negatively affected by the presence of lesions or even from optical disc in detection phase, since it identifies red lesions discriminating regions with low and high intensity. Low intensity regions are related to potential red lesions. On the other, it is possible to find detection methods in literature (e.g., Badea et al. [4]) that carry out firstly the detection of all existing structures within image, and afterwards they remove the optical disc and white lesions. Such approach is more susceptible to imprecisions in detection process. It is important to point out the method presents limitations regarding blood vessels removal and identification of little lesions in image. We observed through our experiments that the detection and removal...
of blood vessels affected both sensitivity and specificity measurements. The phase of blood vessels extraction contributed to sensitivity loss due to the frequent proximity between lesions and vessels. Thus, when the circularity is calculated it takes place the removal of the lesions because several lesions are joined to blood vessels. This is a drawback compared to a method of blood vessels detection that identifies the skeleton tree of them based on their linear structure. Considering the specificity, the blood vessels removal was limited due to little vessels. Particularly, the method did not remove all these kind of vessels from the image. In the image, the pixels corresponding to such little vessels are identified as FP and they decrease the specificity in the proposed method.

Conclusion

We describe a method for detecting red lesions in retinal images. The proposed method comprises a stage which increases the detection accuracy by removing dark structures such as vessel and the macula region, and by means of a further refinement of the red lesions candidate regions. Our experimental results based on the DIARETDB1 public database indicate that our method achieved 75.81% of average sensitivity and 93.48% of average specificity. It shall be observed, that the great challenge in the case of detection of red lesions is to achieve a high average value of sensitivity and specificity. Our proposed method demonstrated this very clearly through a complete evaluation, i.e., without ignoring the main measures of accuracy described in the literature. In addition, it is only when a particular method achieves high sensitivity and high specificity that the good result (i.e., close to the result specified by the ground truth) is reached. Future work will focus on the development of other methods related to the automatic detection of diabetic retinopathy. Additionally, we intend to investigate regarding the use of red lesions along with another retina elements in people identification.

Semi-Automatic Mark-Up and UMLS Annotation of Clinical Guidelines

Matthias Becker*, Britta Böckmann*a,b

*Department of Medical Informatics, University of Applied Sciences and Arts, Dortmund, Germany
*bIMIBE, University Hospital Essen, Germany

Abstract
Clinical guidelines and clinical pathways are accepted and proven instruments for quality assurance and process optimization in the healthcare domain. To derive clinical pathways from clinical guidelines, the imprecise, non-formalized abstract guidelines must be formalized. The transfer of evidence-based knowledge (clinical guidelines) to care processes (clinical pathways) is not straightforward due to different information contents and semantical constructs. A complex step within this formalization process is the mark-up step and annotation of the text passages to terminologies. The Unified Medical Language System (UMLS) provides a common reference terminology as well as the semantic link for combining the clinical pathways to patient-specific information. This paper proposes a semi-automated mark-up and UMLS annotation for clinical guidelines by using natural language processing techniques. The algorithm has been tested and evaluated using a German breast cancer guideline.

Keywords:
Decision Support Systems, Clinical; Natural Language Processing; Machine Learning

Introduction
Clinical guidelines identify, summarize and evaluate the highest quality of evidence and most current data about prevention, diagnosis, prognosis, and therapy, including the dosage of medications and cost-effectiveness [1]. They aim to help healthcare professionals and patients to make the best decisions about treatment and care for a particular condition or situation. The content of a guideline is based on a systematic review of the clinical evidence—the main source of evidence-based care. A decisive factor for the success and use of clinical guidelines is the provision of knowledge at the point of care. The main challenge can be summarized as follows: Imprecise, non-formalized abstract guidelines have to be implemented as concrete processes. The acceptance of clinical decision support systems is only given if they are integrated into the clinical workflow and presented at the point of care [2]. Clinical pathways, tools used to guide evidence-based healthcare, are appropriate for that purpose and have been implemented internationally.

Due to different information contents and semantical constructs, the transfer of evidence-based knowledge (clinical guidelines) to care processes (clinical pathways) is not straightforward. Although there are already several approaches to formalize clinical guidelines to create clinical pathways, the process of formalization and the annotation of terminologies are very complex [3].

For example, during the mark-up step, the extraction of all pertinent guideline recommendations, which should be considered during pathway development, and classification (e.g. medication, procedure, observation, additional information) of this information are done manually by a health professional. Since the guidelines update at different intervals, this time-consuming step must be performed again after each update. The idea is to semi-automate the mark-up process by natural language processing techniques and simultaneously annotate the marked passages by UMLS [4, 5]. This terminology makes it possible to connect the components (generic knowledge and patient-specific information) with semantically rich links in a real-time dynamic manner at the point of care and with less effort [6]. It has been demonstrated that clinical guidelines used as decision support systems significantly improve patient care and are effective instruments to decrease undesired practice variability. However, acceptance of clinical decision support systems is only given if they are integrated into the clinical workflow and presented at the point of care [7]. Model-based approaches to support the development of guideline-compliant pathways, such as PathGuide, enable the formalization of narrative guideline content into care processes.

The development of new tools for intelligent information technology-based text analysis make it possible to access knowledge out of unstructured text and use it, for example, for decision support or research purposes. Most of the available tools as well as terminologies are available in English and cannot be used directly for German text or guidelines. Nonetheless, there are various international approaches. One promising approach is machine learning natural language processing with information extraction techniques [8]. Extracting information from clinical texts has been the focus of a growing body of research in the past few years. One of the fundamental tasks in clinical natural language processing research is to extract clinically relevant entities (e.g. diseases and drugs) by using semantic standards such as Concept Unique Identifier (CUI) defined in the UMLS. One of the most proven natural language processing tools is the open-source natural language processing system for the extraction of information from electronic medical record clinical free-text Apache cTAKES [9]. Apache cTAKES already offers a variety of algorithms for text analysis and information extraction. The system was deployed at the Mayo Clinic and is currently an integral part of their clinical data management infrastructure, and has processed over 80 million clinical notes. It can be normalized to domain ontologies by using UMLS concepts.

Methods
Related Research and Dataset
Dr Katja Heiden developed a software tool called PathGuide for model-based generation of guideline-compliant pathways for use in different Hospital Information Systems [10]. The
classification is done on the basis of the elements of an HL7 meta-model and indicates the content of a narrative recommendation, e.g. medication, procedure, observation, and additional information. This step is supported by an integrated mark-up tool. For example, the guideline recommendation that ‘patients with early invasive breast cancer should have a baseline dual energy X-ray absorptiometry (DEXA) scan to assess bone mineral density’ is classified as an examination observation). Figure 1 shows the integrated mark-up tool by PathGuide.

Figure 1-Mark-up Annotation by PathGuide [9]

The guideline and manually marked path-relevant passages are displayed on the left-hand side. On the right-hand side, a classification can be carried out manually. For this approach, the data model of PathGuide was extended by UMLS and the mark-up was supported by a natural language processing pipeline. For evaluation of the pipeline, an unstructured German breast cancer guideline was used.

Natural Language Processing

Natural language processing is an area of research and application that discovers how computers can be used to understand and manipulate natural language text or speech. The most common approaches to natural language processing are based on machine learning, a type of artificial intelligence that examines and uses patterns in data to improve a program’s own understanding. This research develops a clinical disorder recognition and encoding system by combining a machine learning-based approach for entity recognition with UMLS concept-mapping for German guidelines. One of the most proven natural language-processing tools is the open-source natural language processing system for extraction of information from electronic medical record clinical free-text Apache cTAKES [11]. It currently offers a variety of algorithms for text analysis and information extraction. With major modifications, such as the implementation of the German UMLS database and German OpenNLP models, it can be normalized to domain ontologies (such as SNOMED-CT or ICD 10) by using German UMLS concepts [12]. For pre-processing of German notes, three tiger data trained OpenNLP models were integrated into the natural language processing pipeline. These included a German Maxent Part-of-Speech tagger, Tokenizer and Sentence Detector. For the extraction of UMLS concepts from German clinical guidelines, a natural language processing pipeline with a mapping to the UMLS database is necessary [13]. Once the concepts are identified, it is possible to map the concepts to domain ontologies and international terminologies. In order to process the clinical guideline, a pre-processing step has to convert the guideline from PDF to plaintext.

Terminologies

The UMLS integrates and distributes key terminology, classification and coding standards, and associated resources to promote the creation of more effective and interoperable biomedical information systems and services, including electronic health records. It is a comprehensive list of biomedical terms for developing computer systems capable of understanding the specialized vocabulary used in biomedicine and healthcare. For the natural language processing pipeline, the following German concepts from the UMLS database were integrated into the cTAKES database:

- International Statistical Classification of Diseases and Related Health Problems (ICD 10)
- Universal Medical Device Nomenclature System (UMDNS)
- The International Classification of Primary Care (ICPC)
- Logical Observation Identifiers Names and Codes (LOINC)
- Medical Dictionary for Regulatory Activities (MDR)
- Medical Subject Headings (MeSH)
- World Health Organization—Adverse Drug Reaction Terminology (WHO-ART)

The UMLS was developed by the National Library of Medicine (NLM). NLM produces and distributes UMLS Knowledge Source databases and associated software tools for use by system developers to build or enhance electronic information systems that create, process, retrieve, integrate, and/or aggregate data and informatics research. All UMLS Knowledge Sources and associated software tools are free of charge to U.S. and international users. The German database contains over 200,000 concepts.

Evaluation

Precision and recall are the basic measures used in evaluating search strategies. In pattern recognition and information retrieval with binary classification, precision is the fraction of retrieved instances that are relevant, while recall is the fraction of relevant instances that are retrieved. The evaluation of the adapted pipeline follows the standard metrics of evaluation using F1 (3), i.e. the harmonic mean of recall (2) and precision (1).

\[
P = \frac{\text{true positive}}{\text{true positive} + \text{false positive}} \quad (1)
\]

\[
R = \frac{\text{true positive}}{\text{true positive} + \text{false negative}} \quad (2)
\]

\[
F1 = \frac{2PR}{P + R} \quad (3)
\]

Precision (P) is the number of correct positive results divided by the number of all positive results, and recall (R) is the number of correct positive results divided by the number of positive results that should have been returned. The F1 score can be interpreted as a weighted average of precision and recall, where an F1 score reaches its best value at 1 and worst value at 0.

Results

For semantic data visualisation of the semi-automatic results, the Unstructured Information Management Architecture (UIMA) Annotation Viewer adapted to the cTAKES type-system was used [14]. Figure 2 shows the mark-up annotation results:
The Annotation Viewer on the left-hand side shows the semi-automatic mark-up by the natural language processing pipeline. Unlike PathGuide, the Annotation Viewer uses different colours to represent different Annotation Types (e.g., Diseases, Medication, Symptoms, and Anatomical Mention). On the right-hand side, the Annotation Viewer represents the identified and marked UMLS Concepts and the derived ontologies such as SNOMED-CT, ICD or RxNorm. The natural language pipeline only identifies the concepts that are also present in the UMLS database, without checking whether these are necessary for the creation of the clinical pathway. Table 1 shows the total amount of the manually identified and the semi-automatic identified items.

As noted, the total amount of semi-automatic mark-up and annotated items are significantly more. As discussed above, this is due to the missing check to determine if this item is relevant to the pathway or not. In manual mark-up, the areas that are not used for the creation of the clinical pathway are not marked. This ability is missing from the natural language pipeline.

To find out whether the manually marked areas were identified by the pipeline and were additionally annotated with UMLS, the respective items were analysed. Table 2 shows the results of the semi-automatic mark-up, with outgoing of the manually marked result as the gold standard.

Results showed that 68% of the manually marked items could be annotated by the pipeline through UMLS. The pipeline also obtained a good recall value, especially in diagnosis and therapy. Due to the lack of knowledge about the relevance of items for the creation of a clinical pathway, significantly more items were marked and annotated by UMLS concepts. Consequently, the results for the precision are significantly lower since more false-positive entries are identified by the pipeline. However, the annotation by UMLS is automatically possible and the semi-automatic mark-up can be used as support for creating a clinical pathway.

Discussion

It is important to identify a few study limitations. First, the clinical guideline was created from manually identified items and considered as the gold standard, but this might not be the best process for this guideline. Formalizing a guideline and identifying areas of importance for the clinical pathway are not always clear and can depend on the person doing the formalization. Some of the mark-ups considered as erroneous as compared to the reference could, in fact, come from clinical interpretation. Second, lack of a knowledge database, which is needed for the creation of the clinical pathway, greatly limited the level of precision. In particular, only the words for which there is an entry in the German UMLS database can be annotated. An example of this is the phrase, *patient information*. This is an important step in the clinical pathway and has to be marked in the guideline, but this word exists only in the English version of the UMLS and not as the translated German word *Patientenaufklärung*. This can be attributed to the fact that the English UMLS database (5,571,374 entries) is much more extensive than the German database (217,672 entries). As a result, a learning program must be used to train a currently referenced database with guideline-specific abilities. The challenge is to mark the trained extensions in such a way that an update of the UMLS database is still possible without overwriting new trained entries. This marker is not provided by the cTAKES database. In order to avoid overwriting the new trained entries with an update, it may be possible to provide them with a postfix or prefix. These entries would then have to be excluded when updating the UMLS database. Additionally, there are areas in the guideline that do not fit in to any UMLS concept, regardless of language. For this reason, the next step is to implement a self-learning UMLS database for the German language to improve the results of the pipeline.

An alternative approach would be to formalize the guideline manually without using natural language processing support as mentioned earlier and then annotating the resulting files (e.g. XML files) using natural language processing. In this case, the pre-mark-up would be omitted, but false-positive markings would not arise. It would retrofit an automatic UMLS annotation without the advantage of a semi-automatic mark-up.

In the next development step, the UIMA Annotation Viewer is expanded with a manual mark-up function including a connection to the cTAKES database. This allows the user to insert unmarked words directly into the cTAKES database so that they are identified at the next mark-up. Lastly, there will be Dummy CUI codes for words that are important for the creation of the clinical pathway. This does not affect the annotation of UMLS codes, but these words will be marked as clinical pathway-relevant in the future.

Conclusion

Natural language processing can be used as a pre-processing step that can simplify the mark-up process and UMLS annotation in clinical guidelines to create clinical pathways.
However, a manual mark-up and a manual post-processing cannot be replaced by that pipeline.

Inter-Annnotation Agreement and the Upper Limit on Machine Performance: Evidence from Biomedical Natural Language Processing

Mayla Boguslav and Kevin Bretonnel Cohen

Computational Biosciences Program, University Colorado School of Medicine, Aurora, CO, USA

Abstract

Human-annotated data is a fundamental part of natural language processing system development and evaluation. The quality of that data is typically assessed by calculating the agreement between the annotators. It is widely assumed that this agreement between annotators is the upper limit on system performance in natural language processing, if humans can’t agree with each other about the classification more than some percentage of the time, we don’t expect a computer to do any better. We trace the logical positivist roots of the motivation for measuring inter-annotator agreement, demonstrate the prevalence of the widely-held assumption about the relationship between inter-annotator agreement and system performance, and present data that suggest that inter-annotator agreement is not, in fact, an upper bound on language processing system performance.

Keywords:
Natural Language Processing; Supervised Machine Learning; Evaluation Studies

Introduction

The Code of Ethics and Professional Conduct of the Association for Computing Machinery includes the imperative to share knowledge of the limitations of computer systems (ACM Code of Ethics and Professional Conduct 2.7) [1]. In natural language processing, human-annotated data is the gold standard for most evaluation studies [2], and therefore it is crucial for understanding the limits of our work. It is standard practice to measure the quality of that data by assessing the extent to which humans agree with each other in the task of producing it [3]. This is called inter-annotator agreement (IAA) [4]. A standard assumption in the field is that the inter-annotator agreement establishes an upper bound on system performance [5-10]. In fact, the assumption that it is an upper bound on system performance turns out to be just that—a heretofore-untested assumption. The goal of the work reported here is to test that assumption. We do so by searching for the bound on system performance turns out to be just that—a heretofore-untested assumption. The goal of the work reported here is to test that assumption. We do so by searching for the source for this agreement between the annotators. It is widely assumed that the expected agreement between the annotators if each annotator randomly picked a category for each annotation. Thus, Cohen’s Kappa adjusts for chance to determine how much better the annotators did than chance [13]. Typically, language processing researchers compare the IAA score to the F1 measure obtained by the system, including all of the papers discussed here except for [14], which uses precision (positive predictive value).

The F1 is the harmonic mean of precision (P) and recall (R) (sensitivity). It is calculated on the basis of the numbers of true positives, false positives, and false negatives in a system’s output:

\[
F_1 = \frac{2PR}{P + R}
\]

In the case of annotating linguistic data, it is often the case that the expected chance agreement (Pr(e) in the formula for kappa) is effectively zero, since there is no clear definition of what would count as a false positive, e.g. in the case of any task that requires the labelling of boundaries, such as in named entity recognition or any task involving scope (e.g. syntactic analysis). When this is the case, kappa is equivalent to F-measure, and this observation is the justification for their comparison here [15].

Methods

This paper approaches the assumption of inter-annotator agreement as the upper limit on system performance in three steps. First, we seek to answer the question of whether it is, indeed, a widely held assumption in the natural language processing community. Then, we try to find the source for this

\[
\kappa = \frac{Pr(a) - Pr(e)}{1 - Pr(e)}
\]

where Pr(a) is the observed agreement between two annotators and Pr(e) as the expected agreement between the annotators if each annotator randomly picked a category for each annotation. Thus, Cohen’s Kappa adjusts for chance to determine how much better the annotators did than chance [13]. Typically, language processing researchers compare the IAA score to the F1 measure obtained by the system, including all of the papers discussed here except for [14], which uses precision (positive predictive value).
For all three datasets, we used the Shapiro-Wilk test [17] to determine if they were normally distributed. We calculated the correlation between IAA and system performance in terms of F-measure, reasoning that if the findings are noise, that should be reflected as random variation in the F-measure, the IAA, or both; on the other hand, if it is not just noise, that would be reflected by structured relation.

We then asked the literature search service to find examples of papers that reported inter-annotator agreement and results from a natural language processing system, such that the system performed higher than the inter-annotator agreement.

To search the full text of publications, the service used Google Scholar. Phrasal search for inter-annotator agreement and F-measure and proximity operators to find cases where they occur near each other were used to retrieve an initial set of around 100 papers. Those papers were then examined manually, and any papers in which the inter-annotator agreement was higher than system performance or there was no explicit discussion of the relationship between them were excluded. This resulted in a set of 6 papers that included data on 20 systems that outperformed the inter-annotator agreement.

We next extracted the IAA and system performance measure for all 20 systems described within those articles. To evaluate the possibility that these values were noise, rather than an actual finding, we used simple statistical models to test for structure in the relation between IAA and system performance in three data sets: the systems that outperformed the IAA, other systems that did not, and both combined. The reasoning here is that if the findings are noise, that should be reflected as random variation in the F-measure, the IAA, or both; on the other hand, if it is not just noise, that would be reflected by structured relation.

For all three datasets, we used the Shapiro-Wilk test [17] to determine if they were normally distributed. We calculated the correlation between IAA and F-measure, reasoning that if the papers that report outperforming IAA are just observing noise, there should be no relationship between them. Because most of the distributions were not normal, Spearman’s correlation, a non-parametric test [18], was used to calculate the correlations. The details are available on the GitHub site [16].

### Results

There is no citation that establishes inter-annotator agreement as an upper bound on system performance. Neither we nor a professional literature search service found an authoritative citation for the idea that inter-annotator agreement is the upper bound on language processing system performance. It is often asserted, but we have not found a cited source that establishes it to be the case. None of the papers that explicitly asserted the assumption cited a source for the assertion.

Nonetheless, explicit statements of the assumption in multiple papers demonstrate that this assumption is widespread. We give six explicit statements of the assumption, including in papers by some of the most prominent researchers in the field—see the quotes in Table 1.

Six papers (four from the biomedical domain and two from the general domain) reported at least one system that outperformed the IAA (see Table 2), for a total of 20 systems. Note that generally system performance was measured using F1 measure, so we will use those terms interchangeably. The small number of papers reflects the fact that this is not a commonly reported phenomenon. However, neither is it untested—this was not just a single counter-example, and those six papers reported on 20 systems that outperformed the inter-annotator agreement.

*Note that all articles use F1 for system performance except for [14], which uses precision.

Figure 1 shows the F₁ and inter-annotator agreement for the 20 systems. The Shapiro-Wilk normality test [17] showed that only the system performance measure is normally distributed. IAA is not, and skewed left. Therefore, we calculated the Spearman correlation, which is non-parametric. This showed that IAA and F₁ measure are significantly positively correlated (rho = 0.807, p-value = 8.56 X 10⁻⁶) (see Figure 2).

We then did the same analysis both for systems that did not beat the IAA, and for all systems together. In systems that did not outperform the IAA, neither IAA nor F-measure were normally distributed. There was a significant positive correlation between IAA and system performance (rho = 0.653, p-value = 1.449 x 10⁻¹¹) (see Figure 3).

For the combined data combined for systems that did and did not outperform the IAA, the IAA and system performance were significantly positively correlated, but less so compared to only the systems that outperformed the IAA (rho = 0.513, p-value = 1.81 x 10⁻⁸) (see Figure 4).

We can also see how the medians are affected depending on which systems are included: those that outperform the IAA, those that do not, or both (see Table 3).

Comparing the relationships between inter-annotator agreement and F-measure in the three sets of systems—ones which did outperform the IAA, ones which did not outperform the IAA, and the combination of those two, the relationships were the same—significantly positively correlated. This similarity across the three groups suggests that the cases of outperforming the inter-annotator agreement are not just noise.
Discussion

Providing accurate information to the public about technology and research results—as well as making funding decisions—requires the ability to accurately interpret measures of performance. The data presented here shows that a common standard for assessing natural language processing tools may overestimate their performance: contrary to a widely-shared and hitherto unexamined assumption in the field, the inter-annotator agreement is not necessarily the upper bound on performance in natural language processing. A lack of awareness of this can lead to the belief that systems are performing as well as they can, when in fact they are not.

Based on two literature searches and on the fact that no one ever cites one, there is no authoritative citation for the idea that IAA is the upper bound on system performance—in fact, it has been only an untested assumption. If there is some authoritative source that establishes this, not only have we not been able to find it, but also apparently no one else has, either, since no one cites one.

Despite being an untested assumption, it is nonetheless a widely-held assumption, as shown by the fact that we did not have any problem finding multiple explicit statements of it, some of them by the top people in our field.

Finally, the studies whose results are analyzed in this paper demonstrate that this widely-held assumption is not true. The distributional characteristics of the results—that is, their correlated, rather than unstructured nature—suggest that this is a real phenomenon, and not just noise. We cannot assume that the inter-annotator agreement is an upper bound on system performance, and in doing so, we may be over-stating how good natural language processing systems are.

In some of the papers that reported performance better than the inter-annotator agreement, the authors pointed out explicitly the unusualness of that finding. Some saw this as needing explanation, and they suggested explanations that were consistent with typical assumptions about inter-annotator agreement, such as that low inter-annotator agreement reflects a poor problem definition, an inherently difficult problem, poor guidelines, or—commonly—poor annotators [10; 20; 23-25].

If inter-annotator agreement does not establish the upper bound for system performance, what should we use in estimating the upper bound on system performance? Although a definitive answer to that question is outside of the scope of this paper, we discuss three possible solutions. They are based on changing what metric we use to quantify agreement; on changing who we define as the raters between whom the agreement is being calculated; and on replacing the agreement altogether with probabilistic estimates of a label quality.

One possibility is that we can safely use an inter-annotator agreement if we calculate it as something other than kappa. Although kappa is the most commonly reported measure of inter-annotator agreement, it has a number of problems. Some of these are essentially cultural—although there are a number of ways to calculate the expected chance agreement that is at the core of its claimed advantages, authors rarely report how they calculated the expected chance agreement. Consequently, it is often unclear what the kappa number actually reflects. When combined with the fact that the sensitivity of kappa to the probability of an estimated chance agreement is unstable—above an estimated chance agreement of about 0.5, kappa is extremely sensitive to small changes in the probability of chance agreement, while being relatively insensitive to small changes in the probability of a chance agreement below that value—it is clear that there are many reasons to be suspicious of reliance on this number.

In the previous paragraph we have discussed calculating something other than kappa to characterize the inter-annotator agreement, Bethard et al. [20] suggest changing the definition of the raters, such that rather than calculating agreement between two annotators, we calculate agreement between an annotator and an adjudicator. This may provide an agreement value that is more reflective of the data on which the system will be trained and evaluated, since if adjudicated data is available, that is typically what is used for training and testing. However, a number of conditions must be met for this to be possible—at minimum, there has to be an adjudication step, which is not always the case. Furthermore, changing the definition of the raters between whom agreement is calculated does not answer the question of how to calculate the agreement between them.

Finally, Passoneau and Carpenter suggest abandoning an agreement entirely and building a probabilistic annotation model of label quality [26].

In the larger context of responsible conduct of science, the findings reported here are relevant to the small but growing body of work on the ethics of NLP [27-29]. As noted above, the ethical standards of the Association for Computing Machinery include the responsibility to communicate the limitations of computer systems [1]. In reporting performance, there is a common assumption that metrics that approach an inter-annotator agreement reflect high performance [5-10]. The data reported here suggest that such performance may not be as high as we think it is, relative to the best possible performance, suggesting that this assumption can lead—certainly inadvertently—to conduct that does not meet the Association for Computing Machinery standards.

Conclusion

This paper examines a common assumption in natural language processing. It is shown that the assumption is, indeed, widespread; that there is no established justification for that assumption; and that the assumption is not true. This last point is demonstrated both by multiple counterexamples, and by descriptive statistics that suggest that the counter examples are not random noise in the larger population of published papers on language processing, but rather reflect a real phenomenon. Responsible conduct of science will be enhanced by being aware of this.

Sharing Health Big Data for Research - A Design by Use Cases: The INSHARE Platform Approach

Guillaume Bouzillez, Richard Westerlync, Gautier Defossez, Dalel Bouslimi, Sahar Bayat, Christine Riou, Yann Busnel, Clara Le Guillou, Jean-Michel Cauvin, Christian Jacquelin, Patrick Pladys, Emmanuel Oger, Eric Stindel, Pierre Ingrand, Gouenou Coatrieux, Marc Cuggia

Abstract
Sharing and exploiting Health Big Data (HBD) allow tackling challenges: data protection/governance taking into account legal, ethical, and deontological aspects enables trust, transparent and win-win relationship between researchers, citizens, and data providers. Lack of interoperability, compartmentalized and syntactically/semantically heterogeneous data. INSHARE project using experimental proof of concept explores how recent technologies overcome such issues. Using 6 data providers, platform is designed via 3 steps to: (1) analyze use cases, needs, and requirements; (2) define data sharing governance, secure access to platform; and (3) define platform specifications. Three use cases – from 5 studies and 11 data sources – were analyzed for platform design. Governance derived from SCANNER model was adapted to data sharing. Platform architecture integrates: data repository and hosting, semantic integration services, data processing, aggregate computing, data quality and integrity monitoring, Id linking, multisource query builder, visualization and data export services, data governance, study management service and security including data watermarking.

Introduction
Health Big Data (HBD) is more than just a very large amount of data or a large number of data sources. It also refers to the complexity, challenges, and new opportunities presented by combined analysis of data. Health data collected or produced are now potentially sharable and reusable. They can be exploited at different levels and across different domains, especially concerning questions related to multidisciplinary research. This huge amount of data holds the promise of supporting a wide range of medical and health care functions, including among others clinical decision support, disease surveillance or population health management [1]. This explains the incentive policy of opening HBD around health data science being supported by different public authorities and scientific communities such as OpenData, AVIESAN or Inserm initiatives, as well as European research programs like IMI or Horizon 2020. Recently, strong initiatives have been launched in U.S to enhance utility of health Big Data and finally to enter in the next level of knowledge discovery [2].

In this context, clinical data warehouse (CDW) technology comes forward as one of the solutions to address HBD exploitation. CDW, are becoming increasingly widespread in U.S, being put to use for different purposes including cohort discovery, biomarker detection, feasibility studies or enrolment of patients in clinical trials. Research communities are currently connecting CDW to one another with the aim of creating Clinical Data Research Networks (e.g. PCORNET [2]) or biomedical research network (e.g. Data to Knowledge).

In these networks, data providers such as researchers, health facilities, research agencies or institutions make part of their data available to research community while maintaining data sharing control at all time. Thus, these trusted third-party platforms integrate and open-up scientific or potentially scientific health data [3]. This makes use of these data at a large-scale possible. In France, such platform, that would be able to integrate and share multisource and multiscale big and small health data produced by health institutions for research purposes, does not exist.

This is the aim of the INSHARE French national project; in which different and actual key issues like governance, organizational, and technical factors to perform such data sharing will be explored and addressed. The absolute goal is to facilitate access to data and foster collaborative research and data sharing between researchers and data providers. In this paper, we present and discuss these key issues and approach we are following to design the platform. The approach is driven by real research use cases of high interest for individuals and states.

Background
Data to share: In its large acceptance HBD sources comprise various types of data from structured information such as OMICS data, administrative or billing data, drug prescription data consisting of dates and dosages captured through
standardized ePrescription system, to unstructured and textual data such as clinical narratives that describe medical reasoning behind prescriptions [4]. Beyond data generated by hospitals, several health data sources come from health registries or insurance databases, which are a valuable source of standardized, longitudinal, population-wide data. For instance, the French health reimbursement database (Système National d’Information Inter-Régimes de l’Assurance Maladie, SNIIR-AM) contains individualized, anonymous and comprehensive data for all health spending reimbursements received by affiliated subjects, including basic patient demographic data such as age, gender, medical drugs, and outpatient medical cares – prescribed or performed by health professionals from both public and private practices. SNIIR-AM is also linked via a unique personal health number to the French hospital discharge database (PMSI), which contains diagnostic codes, medical procedures, and admission dates for all hospitalizations. Data from SNIIR-AM is increasingly used for research projects, especially relating to detection of drugs’ adverse effects in epidemiology or clinical research. The designed platform governance models were derived from the SCANNER model and adapted for data sharing.

Sharing barriers: The regulatory hurdles obstructing optimal use of data for research have been extensively discussed within specialised literature [5]. Identified factors are characterized by (i) over-cautious approach among data custodians, many of whom are unwilling to link or share data, (ii) legislators’ failure to consider flexibility required to allow and support such linking and sharing and (iii) incorporation of ‘good governance’ models or intelligent design of working instances not contemplated within the regulatory framework, nor reflecting on the subject [5], [6]. Sethi proposes a model for data sharing governance including (i) guiding principles and best practices, (ii) safe, effective and proportionate governance, (iii) articulation of roles and responsibilities of data controllers and data processors and (iv) development of a training program for researchers that covers appropriate vetting procedures prior to sharing valuable data.

Cornerstone of data sharing and reuse is trust. Therefore, implementing a trustworthy process for handling citizens’ and patients’ health data is a pivotal goal. Based on the definition of a trusted relationship, one party (trustor) is willing to rely on the actions of another party. In addition, the trustor abandons (full) control over the actions performed by the trustee. As a consequence, a trustworthy system is that in which, the trustor can “place his/her trust and rest assured that the trust will not be betrayed”. A system for data reuse should thus prove its trustworthiness by fulfilling the responsibility of dealing with data within the limits of a social contract regulated by policies between citizens and organizations handling the system.

The technological components behind a trustworthy system involve designing and implementing IT tools and services capable of guaranteeing data quality and security while providing interoperability, adaptability, and scalability. Specific projects funded by the EU and by the IMI initiative [7], such as EHR4CR, are dealing with such challenges, with the prospect of defining use cases, tools, technologies and a business model for data reuse. In particular, the EHR4CR business model includes accreditation and certification plans for EHR systems that can be integrated within a system for data reuse. The purpose of data reuse has implications that belong to the realm of policies and regulations, which are essential aspects for establishing trust. How to manage informed consent is one of the key aspects connected to this issue. In fact, current regulations in many European countries, which are similar to the US, with the HIPAA act, assume that consent (implied or explicit) for use of data is strictly limited to the purpose for which data were collected. This may seriously limit the scope of data analysis.

This theme needs to be reconsidered in the light of the existence of a proper, trustworthy system based on an agreement between citizens and healthcare organizations. Specific practical examples of policies for handling data reuse are provided by regional initiatives in Europe, two such cases being the United Kingdom and Catalonia. ISO/TS 14265:2011 provides a classification of different purposes for processing personal health information that can help make policy formulation more granular.

Methods

To design organizational and technical dimension of the INSHARE platform, an iterative and 4 step bottom-to-top approach has been adopted, by analyzing on the ground, existing needs, use cases, and actual difficulties encountered by the project partners. Four partners are involved in the project as data providers: 2 academic hospitals (CHU Rennes and Brest) which provide datamarts from their Clinical Data Warehouse (eHOP-CDW), 3 epidemiologic registries at a regional or national scale.

This approach aims at defining technical and functional specifications, data protection policies and governance for an efficient and valuable data sharing. Furthermore, this approach takes into account the fact that some technological issues have to be addressed and especially the evolution needs for data analysis and security tools in the scaling-up to HBD.

Step 1 - To describe use cases and user needs:

The aim of this step is to define precisely scenarios from an operational perspective, the information workflow and system/actor interfaces that relate to exploitation of health and research data via the INSHARE platform. Relevant scenarios leverage the richness and variability of data sources hosted by the platform in terms of domain, quality, and origin. Herein, the objective is to identify the functional needs, which are expected by different users of the platform: researchers- users, data providers, and internal operators of the platform.

Step 2 - To define data sharing governance and secure access to the platform:

Regarding ethical, legal and deontological aspects, a focus group composed of domain experts and representatives of patient associations conducts this study. According to the state-of-the-art step and specified use cases defined at the first step, the objective is to establish governance guidelines guaranteeing data protection and individuals’ privacy rights. This step includes submission of these guidelines for validation to institutional and regulatory authorities such as the Comité consultatif sur le traitement de l’information en matière de recherche (CCTIRS) and the Commission Nationale de l'Informatique et des Libertés (CNIL), two French authorities in charge of such regulation aspect.
Step 3 - To define INSHARE platform specifications:

The aim of this step is to define a comprehensive description of intended purpose and environment of the platform. These specifications describe what the software does and how it will be expected to perform, taking into accounts the operational scenarios, security aspects, and stakeholders (users, data providers, and data managers) inputs. It also addresses some key issues in relation with data analysis and security. In terms of data protection in the scaling up, special interest is given to data traceability and on how to give back some control to data providers on the data they make available to researchers. On one hand, users have to know of their action accountability and, in another hand, patient or data provider consent for data exploitation duration has to be guaranteed. Database watermarking, a very recent solution [8], is one of the technology actually explored for those purposes.

Each data provider is part of the INSHARE project to bring their knowledge and experience with their respective data. Data providers are thus responsible for supplying necessary data to the platform in order to answer to the use cases. They have to supply all necessary information about data to correctly perform their integration and to subsequently give capability to the platform to provide the best-suited data for each user request.

Results

Use Cases: Three main use cases corresponding to 5 studies and application domains have been identified and chosen to be performed on the platform. Being able to ensure one of them will be of great interest for cares of individuals and populations. Table 1 illustrates for each use case the sources of data, which will be shared and used in the different INSHARE platform studies.

For instance, regarding study on health care trajectories of end-stage renal disease patients, comorbidities are currently collected and registered in the REIN database at initiation of renal replacement therapy (RRT). But occurrence of comorbidities after RRT started is not a mandatory field of REIN [9]. Moreover, no information on prescribed treatments is available in the REIN database. Through the INSHARE platform, the hospital CDW (Rennes and Brest) will be used to collect comorbidities and expensive drug prescriptions while drug exposures will be extracted from SNIIR-AM in order to enrich the REIN registry with accurate comorbidities and medications including standards and dates of occurrence.

Figure 1 – Uses case under the scope of the Inshare Platform

Platform governance:

The governance determines how the range of controls and procedures with contractual obligations work together to ensure an end-to-end secure and trustfully platform, where the security and reliability of data is guaranteed. Indeed, several INSHARE use cases imply to perform Id linkage processing and require the access to identified data (e.g., Epidemiologic registry enrichment). Moreover, all use cases require aggregating data coming from multiscale institutions (local academic hospitals, regional to national registries, and for the SNIIR-AM, data issued from a nationwide database). Some of them imply intensive computation on big volume of data (e.g. signal detection). All these constraints have led to defining a model of governance for the platform adapted to big data sharing. The model we propose is derived and adapted from the Distributed Scalable National Network for Effectiveness Research (SCANNER). It consists of identifying 10 basic requirements: platform and data provider information, institution information, study information, ethical agreements (coming from an independent IRB-like comity), Data Sharing Agreement (from data providers who are involved in the study), approved users (external users and internal operators of the platform), authentication and access, data use, audit and accounting, patient rights, data segregation. In addition, according to the type of personal data, it includes de-identification, data watermarking, individual access, correction, openness/transparency, individual choice, use and disclosure limitation, integrity, accountability, and safeguards. Technology and some others can meet requirements by contracts, attestation of users, or management supervision.

Platform Design:

As a result, we designed the platform architecture shown in Figure 1. This architecture is oriented to meet the different use cases under the scope of the project, and to perform expected data processing while respecting governance framework mentioned above. The platform encompasses services of several weakly coupled components, the whole in a
cloud-oriented architecture. Hereby, we detail some of the key components and services:

**Data repository and hosting component** is a buffer zone where data providers make available required datasets or datamart to share. The core idea is to host in the platform data with the finest granularity and in their most original form, i.e., with the least transformation possible.

**Health big data integration layer** comprises components and services dedicated to data integration and processing. The semantic integration service (SIS) contains information models (i.e., database schemas of the data sources such as eHOP or SNIR-AM) as well as semantic resources either used in the sources or required for semantic integration (reference or interface terminologies, ontologies and mappings) and ensures standards’ interoperability (such as HL7, PN13, HPRIM). SIS provides tools and methods to the other standard components.

**Data preprocessing service** is devoted to data enrichment. It includes NLP tasks and data indexing to make easier extraction of useful information from large-scale data stored across the different INSHARE sources. A core functionality of these services is to execute data processing tasks and to query the data virtualization layer in order to access stored data. The developed engine is also responsible for planning, coordination, and execution of queries to the data virtualization layer in a distributed manner, commercial data processing frameworks and parallel relational database management systems.

**Aggregate computing service** is designed for building online auxiliary indexing and summarization structures based on the incoming data processing tasks and their data requirements. Based on profiling and statistic information of the submitted processing tasks. For instance this service is used to compute from CPOE data, aggregates of drug dose per day, week, stay or globally for a patient or a population.

**Data quality and integrity monitoring**: The INSHARE platform deals with data sources having heterogeneous data quality, from EHRs to epidemiologic registries. Integration process has to manage such quality disparities. This component is dedicated to compute metrics to monitor data quality during the integration process. These metrics are useful to (i) alert data providers and take corrective actions at the data source, (ii) perform more accurate analysis taken into account possible bias due to data quality issues, (iii) improve data quality within the INSHARE platform, each source bringing complementary information. For instance, for the same patient, in and out hospital drug information come from different sources and is registered in different ways (structured and coded data from CPOE or SNIR-AM, text for clinical charts, forms and notes). One source can provide more accurate or exhaustive information to others.

**Id Linking service**: For security reasons, in France, as in most countries, there are currently no patient identifiers that can be used to directly link data from different data sources. Nonetheless, several national programs or initiatives provide researchers either trusted third-party linkage services, or big, pre-linked datasets. This, for instance, is the case of the French hospital discharge database (used as part of the hospital billing system) that matches data coming from all hospitals in France. The SNIR-AM is arguably one of the most noteworthy linked data sources recently opened to the research community. The Id Linking service reuses and provides methods to link data sources using deterministic and probabilistic approaches on common data elements. For instance, DRG data coming from hospital are already linked with the other data of SNIR-AM. EHop CDW includes the DRG data. Even without specific common Id, linking can be performed using dates, groups of diagnosis and procedure codes, and ADT mode.

**Data Governance, study management service and security**: These services encompass tools, procedures [10] and workflow to cover governance requirements and provide continuous data protection, from their acquisition to their outsourcing and mutualization within the INSHARE platform and beyond (e.g., when exported). The idea is to complement current data protection, which mainly relies on security of the information system and which do not make it possible to know if data are used for the purposes originally foreseen, especially when data are outsourced. The protection of digital content we deploy is based on watermarking [8] and crypto-watermarking solutions (i.e., mechanisms that combine encryption and watermarking [11] that fulfill different security objectives, in particular in terms of integrity and traceability (identification of information-leak sources or of end-user misbehavior). If data are protected as long as they are not decrypted, watermarking leaves free access to them and maintains them protected by means of security attributes (e.g., digital signatures, users’ ID, access rights) invisibly inserted or embedded into the data themselves. Moreover, watermarking protection is independent of the data storage format. These data protection tools are designed to take into account strong interoperability constraints so as to: i) provide security resilient to information-processing; ii) make the protection on the data provider’s side compliant with the one used by the INSHARE platform and beyond.

**Multisource Query Builder, Visualization and data export services**: These services are intended to: design and perform complex queries on multisource data; visualize results with different modalities; and, export processed dataset to the end users. From the end user point of view, interaction with the platform consists of submitting a request for a study to the platform. Only certified and authorized operators of the platform will have access to the query workbench for data exploitation and eventually to export required datasets to the end user.

Figures 2 and 3 illustrate the workflow for two scenarios. In the first (Figure 2), a targeted research database is fed by data extracted both from two registries (REIN and Cancer playing the role of data provider) according a study protocol about the association between kidney failure and occurrence of cancer. This protocol, which defines criteria for data selection and variables to extract from the source, and user agreement are submitted to the platform. Figure 3 illustrates how the platform is able to enrich a data source (here the Rein registry) by collecting from a list of patient ID, missing or required data (e.g., comorbidities) from the different sources. In this scenario Rein registry is user of the platform and recipient of data. All along this process, health data is maintained, secured by means of digital content protection tools, with a special interest for data traceability and audit trails.

**Discussion and Conclusion**

The INSHARE project’s consortium made the choice to focus on some of today’s crucial challenges, which, in our opinion, are still not resolved: data quality assessment for research purposes, scalability issues when integrating heterogeneous health “big data” or patient data privacy and data protection. Moreover, adoption of electronic health data is still an active
meet real-world use cases and users needs, on real and massive data. For instance, preliminary tests on adverse drug effect detection have been carried out. In this example, the combination of OrientDB (which is a graph oriented database) with SPARK for aggregate computing has shown promising performance for intensive computing. Nonetheless, applying existent solutions should not be sufficient in the background of the INSHARE project. Indeed, starting from the available massive datasets, a second objective aims to design innovative algorithms and techniques in a prospective way (using a data sciences approach, sharing the statistical and computer sciences skills)

Abstract

The purpose of this vision paper is to identify how data visualization could transform healthcare. Electronic Health Records (EHRs) are maturing with new technology and tools being applied. Researchers are reaping the benefits of data visualization to better access compilations of EHR data for enhanced clinical research. Data visualization, while still primarily the domain of clinical researchers, is beginning to show promise for other stakeholders. A non-exhaustive review of the literature indicates that respective to the growth and development of the EHR, the maturity of data visualization in healthcare is in its infancy. Visual analytics has been only cursorily applied to healthcare. A fundamental issue contributing to fragmentation and poor coordination of healthcare delivery is that each member of the healthcare team, including patients, has a different view. Summarizing all of this care comprehensively for any member of the healthcare team is a “wickedly hard” visual analytics and data visualization problem to solve.

Keywords:

Data Display, Data Mining, Electronic Health Records

Introduction

The role of electronic health records (EHRs) has been described as both transformative and turbulent [1]. There are even arguments as to whether an EHR can be considered disruptive technology (in the traditional marketplace sense without fundamental change in the healthcare business model [2]), or is simply found to be disruptive to clinicians [3].

No longer just for documentation and communication about individual patients among a local healthcare team, EHRs are intended to support improvement in the overall quality and cost of healthcare [4,5]. Today’s EHRs are expected to improve access to data across the continuum of care – irrespective of organizational boundaries [6]. Despite problems with clinical decision support components [7,8], EHRs are also expected to aid evidence-based care using experiential data [9], social determinants of health as related to a given patient [10], and personally supplied health data [11] – none of which have heretofore been included in individual health records. And, when data analytics are available to a clinician (separate from or as a product of an EHR), they must supply evidentiary information in real, or near real time [12].

Significantly less has been written about the environment of use and human factors associated with use – especially cognitive performance [13] and associated workflows. Indeed, a Journal of the American Medical Association (JAMA) Viewpoint in 2016 [14] suggests that “the evolution of EHRs has not kept pace with technology widely used to track, synthesize, and visualize information in many other domains of modern life.” There are a number of technologies that hold promise for improving the human experience in order to derive value from the EHR investment [15]. Some of these are older technologies, such as data display, registries, and registry functionality which typically have not been included in an EHR [16]. Some are newer, such as data/information visualization and visual analytics. The visual analytics discipline was initially founded in 2004 where the science of analytical reasoning with advanced interactive visual interfaces was challenged to analyze overwhelmingly disparate, conflicting, and dynamic information [17]. One of the earliest papers on visualization in healthcare for personal histories was published in 1996 [18].

In general, it is believed that the use of the term data visualization when applied in the literature to EHR systems is the result of a process of visual analytics. Data visualization may be static or interactive. When interactive, visual analytics supports the ability to act on the data in real time to glean additional perspectives. Interactive data visualization also puts control into the hands of the user, where details can be obtained ‘on demand’ [19]. Caban and Gotz [20] define visual analytics as “the science of analytical reasoning facilitated by advanced interactive visual interfaces.” These authors go on to state that “visual analytics techniques combine concepts from data mining, machine learning, human computing interaction, and human cognition.” This paper notes that “visual analytics systems – by combining advanced interactive visualization methods with statistical inference and correlation models – have the potential to support intuitive analysis for all … user populations while masking the underlying complexity of the data.”[20] Finally, the statement made by Caban and Gotz that “the science of analytical reasoning facilitated by advanced interactive visual interfaces” makes the case for the authors to suggest that when a picture is worth a thousand words, data visualization is the picture created by a visual analytics technique applied to the thousand words [21]. The purpose of this paper is to provide a vision of data visualization’s possibilities for leveraging new methodologies and techniques reflecting the diversity of health data and healthcare process.

Methods

A literature search was conducted using the terms data visualization and visual analytics focusing on real time or near real time EHR systems applied to clinical care. We also included the concepts of cognition or cognitive informatics. We avoided clinical decision support as too narrow, and description of tools without application to electronic health record data as too broad. The searches used PubMed. Due to the hybrid nature of visual analytics we also referred to a
The bold contrasting colors between the data, models, knowledge, and visualization are designed to highlight the differences between the different areas of data exploration. The exploration begins with the data. The blue color of the health professional highlights the commonality of the biological underpinnings of all health professionals, however each circle is distinct, as professional training is different. Professional input into the figure is through the knowledge obtained from the models as the preexisting clinical health model will be different for each profession and the knowledge obtained will be different. The thicker lines represent manual steps through out the process, where the thin lines can become automated.

### Data Visualization in the Electronic Health Record

A total of 19 papers were identified that included use cases for data visualization of EHR data.

Ratwani [35] Intuitive visualization dashboards for end users to facilitate exploration of patient safety event reporting systems and analyze trends.

Simpao [36] An alert dashboard was created using override rates to provide rapid-cycle safety information.

Soukakis [37] Visualization of collaborative EHR usage for hospitalized patients with heart failure was used to help strategically guide care coordination for patients at risk for readmission.

Warner [38] A visualization tool specifically designed to be accessible to clinicians enables exploring for “patients like this one.”

Wongsupha sawat [39] Summarization of temporal event data extracted from EHRs of a cohort of patients can be used to analyze disease (congestive heart failure) progression pathways and their outcomes.

Wongsupha sawat [40] Study of the use of a data visualization tool to describe event sequences in patient transfers between (ED, ICU, intermediate care, and hospital ward) departments.

Predominately, and not surprisingly, these use cases focused on what typically are described as high risk clinical scenarios – disease conditions associated with many co-morbidities and likelihood of emergency department use and hospital readmission, or chronic and debilitating conditions that generally lead to complications [41]. While these areas of focus are important, they are atypical and limited in applicability to the overall processes of healthcare delivery. Examples of chronic conditions in need of models include pediatric asthma, chronic kidney disease, heart failure, diabetes, multiple sclerosis, and depression. In addition, predictors for physiologic deterioration and cardiovascular health issues were geared toward maintaining a stable condition. Intensive Care Unit (ICU) data analysis, transfers among care sites, and medication reconciliation are all challenging issues in busy hospitals and frequently the cause of hospital-acquired conditions. Several of the papers identified suggested that there was not only time savings in clinicians attempting to look for “patients like this one” [38] to make more informed diagnosis and/or treatment plans, but efforts to learn from other patient experiences were actually made wherein the past the time required would often have kept clinicians from conducting such an exercise at all. Although not explicitly stated in any of the papers reviewed, collectively there appears to be the suggestion that interaction with data visualization – which can take from 2 to 5 minutes according to several of the papers – is acceptable for complex clinical cases.

While the focus of the literature review was on use of data visualization in association with an EHR, which implies a healthcare encounter (i.e., hospitalization, emergency department service, or office/clinic visit), patients are increasingly interested in becoming involved in their care. Being able to present information to help patients make treatment choices or lifestyle changes in a manner that is accessible for patients can significantly aid consumer engagement in their care. However, to engage this the latent meaning in the health data need to become accessible to non-experts in biomedical science, i.e., the lay perspective. Through cognitively accessible data, patients can engage in meaningful interactions with health experts to clarify and to improve more rapidly with the goal to readily reduce the likelihood of acquiring or exacerbating a condition [42].

Interactive data

The prior data visualization papers did not always include an explicit model, how the data is interrelated (Figure 1). Without models, data is just displayed and interaction is limited. The potential for various models to enable different filters to be applied based on the data needs of individual users or user types could allow a more interactive data presentation. It is well known that as many as a hundred different users may require access to a patient’s health record in a hospital. The use of such modeling to create truly interactive visualization techniques in order to understand the clinical condition of the patient from any given perspective appears yet to have been addressed.

Imagine, for instance, a nutritionist’s view of the patient’s needs as they dynamically change based on the narrowing of the physician’s differential diagnosis for the patient. One challenge unique to healthcare is that the knowledge base of professionals (physicians, nurses, social workers, pharmacists, physical therapists, occupational therapists, dentistry, nutritionist, public health and many more) is very broad. It appears that data visualization could be the means to aggregate and parse such massive knowledge bases by building models that support multivariate uses of data to improve the healthcare experience for patients.

Multivariate Datasets

Visualizing large continuous streams of structured data has been the focus to date, as described above. However, there are a number of other variables often not in such structured format. For example, lab values which arrive semiregularly can be updated as the results change from preliminary to final. Imaging modalities can vary from small size (amount of data) in data such as ultrasound, to the larger size in data including Magnetic Resonance Imaging, Computed tomography (CT), and many others. From all imaging modalities, the radiologist’s interpretation is normally provided in free text. A common viewing technique is either one large table, or in a timeline based approach. The challenge with both is the user is required to model the information mentally to arrive at knowledge. Creativity of clinicians and visual artists is the only limiting factor in creating solutions to these challenges.

Another area of data that needs better modeling and visualization, is the critical thinking of all health professionals. Without visualizing how professionals’ clinical judgement changes with new knowledge, continuously improving treatment protocols and impacting others’ knowledge cannot be achieved.

Visual Thinking

Visual thinking is a way to organize your thoughts and simplify complex concepts. In figure 1, we show how data can be incorporated into both models and visualization to enable visual thinking. Through better models, we better understand the refinement needed to further make better models and incorporate them into better visualizations. The data needs to be mapped through taxonomies and ontologies (invisible to the end user) in order to improve visualization within the EHR that can impact how clinicians can visually think about data to aid healthcare. Users’ interactions with visualization will create new knowledge. Just as knowledge is the application of experience to information, new knowledge will impact each professional based on personal experience. For example, an increase in a pain score (scale from 1 to 10) for a patient could indicate to a physician an additional medication may be needed,
where the nurse may recognize the level of pain as a failure in pain management education, or a physical therapist may identify the pain as the result of a therapy session to increase range of motion. Depending on when the patient’s pain score is assessed and the timing of how the three professionals interact with the patient, all interpretations could be correct, only some could be correct, or none could be correct. Visualizing all of these interactions and building appropriate models across the range of disease states will be a challenge for the next decade. The creativity of the global community is required to solve hard challenges such as integrating multiple health professions into a single multiprofessional intuitive interface for something a common as a pain score and more innovation for the more complex health conditions encountered on a daily basis.

Designing new user interfaces for EHRs by applying these principles and new designs to engage clinicians both in the patient’s working memory (part of short term memory that is concerned with immediate processing) and the health professional’s long term memory is a huge challenge. Data visualization design and cognitive thought is not just about EHR usability criteria issued by United States National Institute of Standards and Technology (NIST). Rather, data visualization design and cognitive thought is about how healthcare professionals interact with the EHR. This paper focuses on a visual thinking process, and how the computer can engage both visual memory (a form of memory related to your visual experience) afforded through data visualization and working memory [43]. But even simple glyphs (icons), loaded with colors, shapes and direction, portray more information for working memory than just a list of data values. [43] For example, most EHR’s list all of the laboratory values as simple numbers on a table. Applying these principals to ordinary laboratory results could improve time and comprehension of these data.

Discussion

The design and artistic thought and expression of models, visualization, and existing knowledge are not incorporated into the current EHRs. With better models of the clinical decision making of health professionals, the data becomes more amenable to visualizations. Through better measurement and representation, deeper knowledge about the patients and the workflow processes can be studied and improved. Through visual thinking research, refinement of the models, and collaboration with biomedical illustrators, a more intuitive and dynamic interface can enable clinicians to treat patients instead of spending hours reading computer screens.

Conclusions

The maturity of data visualization in healthcare is in its infancy. Visual analytics has been only cursorily applied to the healthcare field. Healthcare is one of the most complex of all disciplines, reflecting a diversity of trained professional team members in the care of an individual patient. For example, a single patient could encounter in one hospitalization, several different physicians, nurses, pharmacists, social workers, hospital administrators, physical therapists, occupational therapists, respiratory therapists, lab technicians, and many others. Each professional has a different view of the patient, and everyone contributes to the care of the patient differently. Through visual thinking and models new interactions with the EHR can improve speed of consuming information and memory. Arming these professionals and the patients themselves with visual thinking is a “wickedly hard” problem to solve. As the fields of visual analytics and data visualization mature, the design criteria and improved usability will help improve the treatment of patients.

What Information Does Your EHR Contain?
Automatic Generation of a Clinical Metadata Warehouse (CMDW) to Support Identification and Data Access Within Distributed Clinical Research Networks

Philipp Bruland, Justin Doods, Michael Storck, and Martin Dugas

Institute of Medical Informatics, University of Münster, Münster, Germany

Abstract
Data dictionaries provide structural meta-information about data definitions in health information technology (HIT) systems. In this regard, reusing healthcare data for secondary purposes offers several advantages (e.g. reduced documentation times or increased data quality). Prerequisites for data reuse are its quality, availability and identical meaning of data. In diverse projects, research data warehouses serve as core components between heterogeneous clinical databases and various research applications. Given the complexity (high number of data elements) and dynamics (regular updates) of electronic health record (EHR) data structures, we propose a clinical metadata warehouse (CMDW) based on a metadata registry standard. Metadata of two large hospitals were automatically inserted into two CMDWs containing 16,230 forms and 310,519 data elements. Automatic updates of metadata are possible as well as semantic annotations. A CMDW allows metadata discovery, data quality assessment and similarity analyses. Common data models for distributed research networks can be established based on similarity analyses.

Keywords:
Information Systems; Metadata; Semantics

Introduction
Data dictionaries provide information about content, structure and in some cases, semantics of information systems. In the domain of health information technology (HIT), mostly pharmaceutical companies are equipped with such dictionaries to support the organization of their trial metadata, the creation process of case report forms (CRF) [1] and to semantically enrich CRFs’ data elements with domain specific variable names based on e.g. the Study Data Tabulation Model (SDTM) [1] of the Clinical Data Interchange Standards Organization (CDISC). In the healthcare domain data dictionaries as well as metadata registries are also able to support the creation process of documentation structures within electronic health record (EHR) systems [2, 3].

A further use case of data dictionaries is the data discovery process within an information system infrastructure. This presupposes that metadata from relevant clinical IT systems is included and structured in a data dictionary. A catalog of available healthcare data is a great advantage to reusing routinely collected data for secondary purposes. For instance, clinical trial feasibility analyses, patient identification and recruitment or the execution of trial documentation can be supported with data from EHR systems or data warehouses [4, 5, 6, 7, 8]. Furthermore, a prerequisite for the secondary use of healthcare data is its quality, the availability of desired elements and an identical meaning of already captured information within routine HIT systems [9].

Most of these projects underwent a laborious and time-consuming process of discovering desired data within clinical primary systems to prepare data exports. Since medical data are far away from being 100% structured, projects like SHARPn or cloud4health additionally focus on processing of free text clinical notes with natural language processing (NLP) techniques [10, 11].

Clinical research is oftentimes performed in a multi-center setting where data from several sites must be identified and analyzed. To achieve semantic interoperability and to identify matching data elements, it is essential that metadata of all participating systems are semantically annotated with codes of medical terminologies, [12] such as the International Classification of Diseases (ICD), the Systematized Nomenclature of Medicine Clinical Terms (SNOMED-CT) or the Unified Medical Language System (UMLS).

Data dictionaries or metadata registries can provide information about data elements and facilitate semantic annotation, which is usually not possible within clinical IT systems. However, populating such a metadata registry is mostly performed manually. Since EHR systems are built with a heterogeneous and proprietary database structure, it is impossible to have one schema for obtaining metadata information from several systems. On the other hand, such systems are not carved in stone, which means that data elements and templates are frequently modified. Given the vast amount of data elements (>1,000 per EHR system), it is almost impossible to manually administrate and synchronize the content of a data dictionary with reasonable efforts and in an appropriate period of time.

Data quality is a key issue for the secondary usage of medical data, especially for those data elements that are most frequently used in clinical trials [13]. Important aspects of data quality are origin, completeness and correctness [9], yet most data dictionaries do not contain any information about the quality of data which they are referencing to because a connection to the clinical IT systems is missing. Due to this fact, it is not possible to prepopulate (research) data warehouses or other applications with exported, predominantly structured patient data.

For several years, so-called distributed research networks are being established to conduct clinical research in cooperation...
with different national or international institutions. Research network infrastructures such as PopMedNet, ODHSI or i2b2 SHRINE are based on a defined common data model or a core ontology to which clinical routine data is mapped \[14, 15, 16\]. Data queries can be performed based on a selection of these data schemata.

However, all of these research infrastructures require data that must be discovered and extracted from primary clinical IT systems to be populated. These tedious and time-consuming tasks of manual metadata processing and quality evaluation steps lead us to our study objectives. We aim to develop an automated generation approach for a clinical metadata warehouse (CMDW) based on HIT systems. The CMDW should serve as an intelligent metadata registry, which facilitates the identification, data quality assessment, and exporting process for the reuse of routinely collected medical data.

Methods

Diverse specifications for metadata models were analyzed such as: the ISO/IEC 11179-3:2013, openEHR, Clinical Element Models and the Operational Data Model (ODM) of CDISC \[17, 18, 19, 20\]. As a result, a generic metadata model was created to store system-specific information, templates (documentation forms), data elements, data quality measures, and relevant parameters to extract data from clinical IT databases. Additionally, permissible values for data elements and semantic annotations of all relevant entities within the CMDW were stored. MySQL was used as database and Java for the implementation of the CMDW.

Data structures in clinical IT systems are mostly organized heterogeneously. Therefore, a generic and universal approach for extracting meta-information from medical databases is essential in order to handle the diversity of systems. In this regard, we considered different schema matching approaches assembled by Rahm et al. \[21\]. For this step, we used Talend Open Studio – Data Integration \[22\]. This Extraction-Transform-Load (ETL) tool includes a comprehensive library of different database input and output connectors, which allows complex matching of definitions. Implementation in Talend was enhanced with a self-written Java code.

EHR systems of two major university hospitals (Agfa ORBIS from two sites and GE Healthcare Centricity Perinatal from One site) in western Germany were selected for the proof-of-concept of the CMDW. Database structures regarding templates and data elements were analyzed and a schema matching pipeline for the CMDW were developed.

Ethical approval was not required since only metadata parameters of EHR systems were processed to evaluate the software tool.

Results

The CMDW Data Model

We chose parts of the conceptual data model of the ISO/IEC 11179-3:2013, which specifies the structure of a metadata registry as basis for the database model of the clinical metadata warehouse. Adaptations were made in terms of the respective clinical IT system and are illustrated in Figure 1. Due to historical reasons, the documentation structure in most EHR systems is based on templates that are filled out for different purposes. Hence, a system contains one or more templates, which again comprises several data elements. Departments are modeled in relationship to these templates to obtain additional information regarding the disease area of each template. Therefore, templates can be referenced to themselves in order to allow modelling of dependencies between closely related main- and sub-templates. According to the ISO 11179 standard, data elements may contain a value domain that includes a list of permissible values (value sets) as options from which to choose. A data element and value domain are then linked in the common circle with the data element concept and conceptual domain classes. To address the assignment of semantic codes, a link between code-system-codes to templates, data elements, value domain and permissible values is established. Lastly, codes are assigned to a specific code system.
template, sub-template associated with other templates, etc.), usage status, version, and system internal ID. Next, data elements were extracted and saved with their relationship to the templates. Again, internal ID, name, description and data type were stored. Then a link to the medical departments was created and permissible values were extracted. Semantic codes were not assigned due to missing annotations in the source systems. This process needs to be performed manually or semi-automatically by eligible programs.

This ETL pipeline can be modified with respect to system specific metadata schemata of all relevant entities. Using Telend Open Studio, this process took approximately 14 seconds to automatically insert all metadata information from one EHR system. The same pipeline can be applied to update the metadata directly, taking several minutes to check for new, deleted or modified entities in our proof-of-concept setting.

Metadata from three EHR systems were integrated into the CMDW. The first EHR system contained 8,135 templates which were referenced to 37 departments and 155,480 data elements. A smaller quality assurance system contained 83 templates and a catalog including 6,102 available and unique data elements. The EHR system of the second site comprised 8,012 templates and 148,937 data elements. All of these were attached with system internal IDs to enable patient data exports into a data warehouse for further analyses and to facilitate an automatic calculation of data quality. To assess completeness for a patient data element, the amount of filled data elements was divided by the total number of patients for a defined time period (e.g. current year).

**Overall System Architecture**

To not only comply with local and national data protection laws, but also with the issue of data sovereignty, we decided to choose a distributed decentralized approach for the architecture (see Figure 3).

![Figure 3 – Architecture of the Clinical Metadata Warehouse](image)

Metadata from clinical IT systems was matched towards the site central CMDW database and transferred. The CMDW is a repository that contains cross-references and meta information from different IT systems. CMDW allowed browsing through the data inventory of all elements with the option to filter for specific medical departments. Internal database IDs of each EHR system were stored in the CMDW to perform data quality analyses and patient data exports into a common data model, such as OMOP (from OHDSI), PCORnet (from PopMedNet), or a clinical or research data warehouse infrastructure. Accessing patient data in a centralized architecture would not be feasible due to data protection laws.

**Discussion**

The Clinical Metadata Warehouse enables automatic generation of data inventory, which is populated with metadata of any primary clinical IT system. It substitutes the previously tedious, time-consuming and manual process of establishing such an inventory. Metadata within the CMDW can be updated automatically, which is a major advantage due to the frequent modifications of clinical IT systems. Common metadata registries or data dictionary solutions often contain only a limited predefined set of data elements for a specific purpose. With a clinical metadata warehouse, not only can selected data elements be considered, but also the full set of structural data contained in HIT systems.

Schema matching is performed with Telend Open Studio [21], which is a flexible and powerful ETL tool for processing and manipulating data between arbitrary sources and targets. For the metadata integration into the CMDW, other ETL tools or schema matching approaches are also feasible. A compilation and evaluation of further toolkits that support matching of schemata is described by Bellahsene et al. [23].

Sun et al. are following a similar approach using ontologies and semantic web technologies [24]. Their Semantic Data Virtualization solution is also an intelligent layer between non-semantically enriched EHR source systems and data consumers. In this layer, source data is mapped to RDF (Resource Description Framework) data with semantics. They mention the burden of common data warehouse approaches to keep the data synchronized between the data source and the target warehouse [24]. Similar to this work, Mate et al. also used an ontological description layer for their EHR data and they are also able to automatically generate SQL queries for data extraction [25]. However, all of these promising approaches suffer from the drawback of manual association and extraction of metadata.

Overall, metadata registries also support the creation process of CRFs in clinical trials [26, 27]. Harmonized data elements and documentation templates could be reused to create comparable results and to reduce the time and efforts for developing clinical trial documentation. Pharmaceutical companies such as Amgen, Lilly, Novartis or Roche maintain a metadata registry with semantically annotated data elements. These elements are mostly annotated with codes of the SDTM of CDISC, which are used for submission of clinical trial data to regulatory authorities.

Data dictionaries or metadata registries have a substantial effect on data sharing across clinical systems, which is also supported by Hicken et al. [28]. In this regard, clinical research networks such as PopMedNet, ODHSI or i2b2 SHRINE facilitate the definition of common data models or core ontologies to define data points that could be queried via a comprehensive network of institutions. The CMDW approach is able to support such research infrastructures by identifying relevant data points in EHR systems and fostering the data population process of data warehouses or other research infrastructures.

**Strengths and Weaknesses**

The ISO 11179 standard was chosen for the CMDW because it was effective in related work [29]. In addition, it is widely used in diverse projects such as the National Cancer Institute’s
caDSR (Cancer Data Standards Registry and Repository) [2], Australia’s METeOR (Metadata Online Registry) [3], and USHKR [4].

Currently, both CMDWs (one for each site) are only populated with data from three EHR systems. Extracting data from EHRs for quality evaluation or secondary purposes greatly relies on the underlying structure of the data model. It is likely that other systems have a different database structure, making the automatically generated SQL queries for data extraction inoperable. Therefore, we are working on a general approach for mapping metadata with clinical data tables.

### Further Research

Since most EHR systems do not provide semantically annotated data elements, the annotation task could be supported by the CMDW in the following ways: (1) manually adding semantic codes for a corresponding data element; (2) implementing a CDISC ODM export for certain forms to support reusing existing elements and semantic annotation; (3) developing an ODM importer to update corresponding elements; and (4) integrating semantic annotation tools, such as CTAKEs [5] or MetaMap [6] to support the coding process of metadata elements.

Additional attention should focus on the quality of the schema matchings. Different “automatic” schema matching approaches exist [21], which could support the process developing guidelines and testing mechanisms to evaluate the mapping process of EHR databases.

Lastly, the identification of redundant routine data should be supported based on metadata content of all systems available within the CMDW. This could be promoted by tools and methodologies that are implemented in ODMSummary [30]. Semantic codes, names and permissible values are used for the comparison to decide whether two data elements are identical, matching, and transformable, etc. These results could be used to improve routine clinical documentation by harmonizing documentation structures and reusing previously entered patient data.

Further research will emphasize the standardized connection between data warehouses and different research infrastructures to evaluate the practicability of this approach.

### Conclusion

The automatic generation and update of a clinical metadata warehouse based on EHR systems is feasible and supports the identification and evaluation of potentially relevant patient data for secondary purposes. Given the large number of data elements in EHR systems, this approach is advantageous to metadata registry approaches with a limited manual set of data elements.

Abstract

This paper proposes an automatic classification method to detect glaucoma in fundus images. The method is based on training a neural network using public image databases. The network used in this paper is the GoogLeNet, adapted for this proposal. The methodology was divided into two stages, namely: (1) detection of the region of interest (ROI); (2) image classification. We first used a sliding-window approach combined with the GoogLeNet network. This network was trained using manually extracted ROIs and other fundus image structures. Afterwards, another GoogLeNet model was trained using the previous resulting images. Then those images were used to train another GoogLeNet model to automatically detect glaucoma. To prevent overfitting, data augmentation techniques were used on smaller databases. The results demonstrated that the network had a good accuracy, even with poor quality images found in some databases or generated by the data augmentation algorithm.

Keywords:
Glaucoma; Retina; Neural Network (Computer)

Introduction

Glaucoma is a lesion that occurs inside of the optic nerve, which can cause low vision or even total blindness. Currently, this lesion has no cure, but an early diagnosis with treatment can prevent the disease progression [1] [2]. One of the approaches used to detect disease is called ophthalmoscopy. This examination may generate a fundus image, which is used for this work. Currently, the detection of glaucoma is done manually by retina experts. They use the ratio between optic nerve size and lesion size, to diagnose the presence and severity. It is a process that takes time, and the lesion is not always clear. This work proposes to perform this task automatically. To perform this task, we have to deal with some challenges, namely: very subtle lesions, poor image quality, and illumination problems. There are related works that extract the size of the optic nerve and the lesion to perform this classification; others use machine-learning methods as neural networks for this purpose. This work aims to apply a robust neural network, developed to deal with hard image classification challenges, in order to overcome many of the problems presented previously. This paper presents a summary of some similar works, description of images datasets used, methodology applied, and the results. For automatic classification, two methods were developed: one to find the region of interest (ROI), optic nerve, in the fundus image and another to classify this region between healthy and with glaucoma.

Chen et al. [3] described a method that uses a neural network with four hidden layers. The input layer accepts images with a dimension of 256x256 and three color channels. The datasets used were artificially augmented using random cropping techniques and mirroring. The work performed two experiments using two image bases, (1) The ORIGA-light, which has 650 images and, (2) SCES, which has 1676 images. The first experiment used 99 ORIGA-light images to train the network and 551 for test. The second used all the ORIGA images to train the network and all of the SCES for test. The accuracy of both experiments was 83.12% and 88.7% respectively.

The method described by Sheeba et al. [4] also uses a neural network, but with two hidden layers. There is no clear information about the private dataset provided by Giridhar Eye Institute in Cochin. It consists of 20 images with unknown ground truth, where 28 have glaucoma and 12 are normal. These were processed using erosion and dilation techniques, where the dilated image is used as background and subtracted from the grayscale image obtained. The resulting intensity is adjusted, and then it is converted to binary values by thresholding the optical disc region. The network was trained by using 20 images with unknown label, and tested in the 40 remaining images. They reported that 34 images were classified correctly.

Zhang et al. [5] consists of an online repository of fundus images. The goal is to provide a way to share those images with the public. Researchers also can benchmark their algorithms. A segmentation and classification tool was developed to assist in the construction of the image database. At the date the article was published, the database was composed of 650 images, delimited by specialists. The ratio between the size of the excavation and the size of the lesion was used for classification. The detection of the region of interest was performed automatically. The first stage is the preprocessing of images, like fringe remove. The fringe happens due to patients not putting their eye so close to the capture machine, generating a light entrance by the edges. This light input hinders the ROI’s detection, since it is done using the centroid of the brightest part of the image. This method has 96% accuracy according to the article. In cases where ROI is not found by the system, the user can manually select that region.

Considering the previous works, we noticed that literature already presents works using neural networks, to detect the presence of glaucoma. However, the results with good accuracy are based on good quality images. The purpose of our work is to perform this detection even in images with low contrast, high amount of noise and low resolution. And, to detecting the ROI of those images using a robust neural network.
Materials and Methods

Image Databases

We used four public image databases that were used for training and validation of the network. The first database, High Resolution Backgrounds (HRF) [6], was composed of 45 fundus images, divided into 3 groups of 15 images. A group of images had glaucoma, while the other groups had healthy eyes and, the last, diabetic retinopathy. For the test and validation, only the groups with glaucoma and normal images were selected.

The remaining three databases, RIM-ONE r1, RIM-ONE r2 and RIM-ONE r3, were part of the work done by Fumero et al. [7]. RIM-ONE r1 and RIM-ONE r2 were composed of ROI images and RIM-ONE r3 of stereo fundus images. The first database had 40 images with some degree of glaucoma and 118 healthy images, while the second had 200 images with glaucoma and 225 healthy images. The third had 74 images with glaucoma and 85 healthy images. Each image has a ground truth delimited by a specialist. For the third database, the stereo images were divided in two parts and only the diagnosed part was used in the experiment.

Deep Learning

Artificial neural networks are part of a set of techniques in the Machine Learning area. This technique was inspired by the learning process of a biological brain, and is constructed using a fully connected neural network. Briefly, each neuron receives input signals from several sources, as well as from other neurons. Each entry is multiplied by a value, called weight. All results are then summed, and verified in a function that decides whether the neuron should send a signal ahead. The learning occurs by adjusting those weights. When a set of inputs gives a wrong output value, the weights are adjusted to make that output correct. Trying not to disturb the result of another set of inputs [8]. The depth of an artificial neural network is measured according to the number of layers between the input and the output of a network, they are called hidden layers. An input signal passes through the network until the last layer, called output, is reached. The last layer gives the prediction of that input signal. A larger number of hidden layers allow for the classification of more complex data, such as images [9].

Deep learning is the process of training multi-layered neural networks. To facilitate this process, we will use an open source framework developed by Google called Tensorflow [10]. It is the second generation of a large-scale machine learning system developed by Google. The system originated from a project called Google Brain started in 2011, where they built the DistBelief, which was the first generation. Tensorflow uses tensors, a multi-dimensional array, to represent data as images. Graphs are employed to represent the flow of operations, where each node represents an operation with zero or more tensors. This framework has implementations of several types of algorithms, mathematical models and specific functions optimized for the training of neural networks. It also provides a practical way to use a graphics processing unit (GPU) to accelerate the training process.

An existing neural network model, called GoogLeNet [11], was used. This model was developed by Google and competed in the ImageNet challenge from 2014, whose objective was to classify about 1.3 million of images in one of the 1000 different classes. The goal of Google was to create an efficient network that could be run even with low computation resources. Some techniques employed like batch normalization, residual connection and factorization allowed for increased accuracy while maintaining performance. The network can be acquired previously trained, with the pre-defined weights. For this work the network was modified to train only a number of classes needed to solve some problems. The weights were maintained to use the principle of learning transfer [12].

Region of Interest (ROI) Detection

Finding manually the ROI of each image, from a large image database, is a hard process. An algorithm was developed to automatically detect this region. This is based on object detection works using neural networks from Malisiewicz et al. [13], Sermanet et al. [14] and an ROI detection work from Xu et al. [15]. A neural network was trained using the GoogLeNet model to classify images into two categories: region of interest or background. For this process, 107 images from ROI and 4693 from other fundus regions were taken from HRF database. An algorithm was made to make those crops, and they were manually classified. It was not a difficult task, because the crops were sequential. The network was trained and performed at about 99% accuracy, distinguishing ROI images from other structures from fundus. This high detection accuracy is due to the distinct characteristics presented in the images.

To find the region of interest within the image, an algorithm was developed that uses sliding windows to scan the image in search of that region. Each window has size proportional to the size of the image. For each window it is checked on the previously described network if it is over the region of interest. If it is then the coordinates of this window are saved. If there is more than one case where this happens then a suppression method based on Malisiewicz et al. [13] and Xu et al. [15] is used, to avoid cases like that of Figure 1, where each window detects a part of the region of interest. This leads to loss of accuracy, since we need the whole region for classification.

Data Augmentation Process

The data augmentation process consists of adding deformations and noise to a data set, with the purpose of increasing the amount of data available for training. Providing a better accuracy to predict data from other datasets [16]. This technique is often used in small datasets, in order to prevent the network from eventually learning characteristics that are not relevant to classification, such as: bright images being classified as glaucoma and low contrast images as normal. It is a process that also prevents overfitting, which is a process where the network begins to decorate the images instead of learning about them. This also causes the network to have a good accuracy in the trained dataset and bad accuracy in others. The work proposed by Wu et al. [17] demonstrates the efficacy of this process to eliminate such problems presented previously, where several transformations in images are used for the learning processes focus on key features in the images.
Figure 2 – Image resulting from ROI extraction algorithm  
a) Extracted ROI from HRF database. Due to the small amount of images available in this database, transformations were applied. b) Results from data augmentation process.

In this work, a rotation of 90, 180 or 270 degrees is randomly applied on each image, as well size rescaling, gamma variation and addition of Gaussian noise. We can apply this process several times in an image. For each iteration we add an image to the training database. Figure 2 demonstrates an example of an image being transformed in two extra images for the training.

Image Classification

Figure 3 – Dataset training workflow

For the glaucoma classification, a neural network also based on the GoogLeNet, was trained. The training process is presented in Figure 3 and was applied to all image databases. First, we have to verify if it is a fundus or ROI database. The images must include the ROI for the classification. If it has fundus images, then all its images go through the process of ROI detection, described earlier. This process transforms a set of fundus images into a set of images of ROI images. Then we can verify if this dataset contains the minimum amount of images, to avoid problems like overfitting. Databases with less than 100 images per category were classified as "few images". In this case the image augmentation algorithm is used to expand the quantity of this category into an arbitrary value greater than the minimum value. When the quantity is good, the database is trained in the network. The processing was applied to HRF, Rim-one-r1 and Rim-one-r3 databases. The HRF database went through the data augmentation process, turning its 30 images into 330. The Rim-one-r1 database glaucoma imaging class also went through this process, the number of images increased from 40 to 120. The Rim-one-r3 database went through ROI detection process.

Experimental results

The results obtained in this experiment are shown in Table 1. They were obtained by using 10% of dataset images to validate the accuracy of network. These images were randomly selected and were not used for neural network training. This helps us to evaluate a network more precisely, by simulating images from other image databases. The training process used 5000 training steps, the number of times a set of images from the data set passes through the network. And with a learning rate, sensitivity adjustment in weights, at 0.01 per update. Training each dataset took about 7 minutes using a GeForce Gtx 1070. For the final test, involving all the image databases, the artificially generated images, generated by the data augmentation algorithm were removed.

We obtained a result close to the experiment described in the work done by Chen et al. [3], but with different databases. It is a satisfactory result, considering the amount of images considered difficult for this classification, such as: large variation in brightness, much noise and ROI barely visible. Some images are considered problematic are presented in Figure 1. There are no post-processing techniques to improve the quality of images. As well neither the common practice of removing blood vessels from those images.

Figure 4 – Examples of challenging images, due to low contrast or much noise.

Conclusion

In this paper a deep learning method was used to detect the presence of glaucoma in the fundus images. The GoogLeNet neural network model from Google was used to accomplish this classification. It was able to detect the presence of glaucoma even in images where it appears only subtly, and in images with very low quality, generated by data augmentation. We obtained 90% accuracy on HRF database, RIM-ONE r1 with 94.2% accuracy, RIM-ONE r2 with 86.2% accuracy, and RIM-ONE r3 with 86.4% accuracy. The combination of all
databases resulted in 87.6% accuracy. To increase the amount of data of some networks, helping the training, a data augmentation algorithm was used. For the extraction of ROI from fundus image databases an algorithm was developed to detect this area. For future work a pre-processing can be done on the images of the databases, as well as expanding the number of databases of images for testing.

Mining Adverse Drug Reactions in Social Media with Named Entity Recognition and Semantic Methods

Abstract

Suspected adverse drug reactions (ADR) reported by patients through social media can be a complementary source to current pharmacovigilance systems. However, the performance of text mining tools applied to social media text data to discover ADRs needs to be evaluated. In this paper, we introduce the approach developed to mine ADR from French social media. A protocol of evaluation is highlighted, which includes a detailed sample size determination and evaluation corpus constitution. Our text mining approach provided very encouraging preliminary results with F-measures of 0.94 and 0.81 for recognition of drugs and symptoms respectively, and with F-measure of 0.70 for ADR detection. Therefore, this approach is promising for downstream pharmacovigilance analysis.

Keywords:
Social Media; Pharmacovigilance; Data Mining

Introduction

The rapid expansion of the Internet and social media is changing the way people gather information about disease and treatment, as well as how they share personal health experiences with others [1]. The Digit in 2016 [2] reported that, in France, 86% of the population are active internet users. This proportion is higher than Western Europe’s average (83%) and slightly lower than North America’s average (88%). Various questionnaire statistics [3-5] showed that a large proportion of French people (46% to 71%) use the Internet to seek medical or health related information. Many people also use social media, such as forums, to communicate with others with the same health concerns and share information related to their illnesses, feelings, medication use and many other aspects [6], which offers promising opportunities for public health surveillance with a rich internet-based, patient-generated source.

The World Health Organization (WHO) defines Pharmacovigilance as “the science relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problems”. It begins during clinical trials and continues after the drug is released onto the market.

However, researches have progressed using (i) various data sources, such as forum messages [16;17], Twitter micro blogs
define all discussions quoting one of the key words, then forums. The extractor uses the names of drugs as key words to structure was then applied to extract messages from these sites were selected through search engines and the NET scoring Tool [21].

An extractor targeting patients’ messages using the HTML constitution. The preliminary results are then discussed.

Materials and methods

Corpus

With the objective of extracting ADRs reported by patients on social media, we selected four French language, health related web sites:

- www.atoute.org
- forum.doctissimo.fr
- sante.medicin.journaldesfemmes.com/forum/
- www.e-sante.fr/forums.

These sites were selected through search engines and the CISMef web site, which is a catalog and index of French health resources on the Internet, and were evaluated using the Net scoring Tool [21].

An extractor targeting patients’ messages using the HTML structure was then applied to extract messages from these forums. The extractor uses the names of drugs as key words to identify all discussions quoting one of the key words, then extracts and cleans the messages from the discussions (removing useless information, like ads, signatures and quotations). We selected 50 drugs of interest as input key words, and for each of these drugs, 20 discussions were randomly picked and extracted. This extraction conducted to the identification of 325,435 messages published between 2002 and 2014, corresponding to 967 distinct discussions.

The analysis showed that nearly 50% of the messages explicitly mentioned at least one symptom, and this ratio is in-between that of general forum posts (24%) [22] and that of drug reviews (80%) [23], which confirmed that our selection and evaluation of web sites and extraction were effective.

Lexicons

The thesaurus RacinePharma, which includes 5164 drug names, was used to identify drug mentions. This terminology is created by CISMef and Service d’Informatique Biomédicale du CHU de Rouen (SIBM) and updated monthly according to the French Base de Données Publique des Médicaments (BDPM), which ensures that it covers all medications on the French market that might be mentioned on social media.

Medical Dictionary for Regulatory Activities (MedDRA) version 15.1 was used to identify medical terms including symptoms, signs, diseases, diagnoses, names and results of analysis etc. In this article, we will use “symptom” to refer to all these terms in order to facilitate writing. MedDRA has a five level structure with a classification in 26 medical disciplines (SOC – System Organ Class), in HLGT (High Level Group of Terms), HLTT (High Level Terms), PT (Preferred Terms), and finally LLT (Lowest Level Terms). The coding of ADRs is done by the LLT, which includes synonyms, lexical variants, sub-elements, familiar expression or “old” terms, thus suits for our study. On this basis, we put in place a strategy to automatically overcome orthographic variations or missed/added terms into the LLT, thus built an extended version of MedDRA in order to increase the coverage without predicting all lay vocabulary in social media. When assessing the performance of automatic recognition of symptoms, we decided to consider the PT level, which clusters the synonyms or lexical variants that might be used by different posters. For example, if we select the PT “anxiety” to evaluate, recognitions of all LLT under this PT, like “worry”, “anxiety”, “anguish”, would be grouped and examined together. As MedDRA is a directed acyclic graph, there may exist multiple paths for the same entity. For example, the PT “scar” belongs to SOC “skin and subcutaneous tissue disorders” and also SOC “injury, poisoning and procedural complications”. In such situations, all possible hierarchies would be considered in the same manner.

Annotation

The Smart Taxonomy Facilitator (STF) Skill Cartridge™ developed by Expert System was applied on the initial corpus. It combines a rule-based approach and a dictionary-based approach The latter includes two main technologies: (i), Fuzzy Term Matching, to take into account possible variants of the terms present in the taxonomy, thus reducing the number of false negatives; (ii) Relevance Scoring, which applies a series of heuristics that assigns a score to each extracted concept, and thus eliminates the least relevant concepts in order to reduce false positives. STF also exploits lexical labels (part-of-speech tagging) to address ambiguity issues.

We integrated in the Skill Cartridge the domain specific dictionaries (RacinePharma and MedDRA) and some internal rules established by our pharmacovigilance experts and text mining experts. Then the fuzzy matching parameters were adapted respectively for drug and symptom recognition.

ADR corresponds to a ternary relationship between (i) a patient and (ii) a symptom related with (iii) a drug through a causal relationship. We identified the linguistic patterns that corresponded to the five major semantic relations between
these three entities: administration (take, test, try, treatment, intake of, etc.), causal relationship (cause, give, result of, since, because of, etc.), sensation (suffer, feel, etc.), drug stop (stop to avoid, to arrest, etc.) and intolerance (endure, allergy, etc.). With the pre-defined linguistic patterns, the ADR Skill Cartridge™ is able to identify multiple relationships between one or more drugs and/or symptoms within one sentence.

**Evaluation**

**Protocol overview**

ADR mining from social media may have two different utilizations: (i) routine signal detection for public health and surveillance; and (ii) focused drug- (or symptom-) signal detection, mainly for pharmaceutical industry. We established a protocol to evaluate the performance of the recognition of drugs, symptoms and their relationships in those two contexts. We will describe in the next sections (1) the constitution of sub-corpus, i.e. selection of drugs and symptoms of interest and determination of sample size, (2) the establishment of gold standard, i.e. manual annotation and the guideline of manual annotation, (3) the statistics analysis for comparison.

**Data sets**

We expected to evaluate the general performance on all identified drug and symptom mentions, and also the performance on certain specific concepts. We therefore selected 12 drugs, including the most frequent in the corpus, the most sold in France in 2013, the most interesting according to the pharmacovigilance experts and we selected some drugs randomly. We selected 9 symptoms, based on similar principles, i.e., the most frequent, the most interesting and some randomly picked ones. For each selected concept, the sample size is calculated under the hypothesis of precision (or recall) = 0.5 ± 0.15, with a significant level of 0.05. The posts containing at least one of the selected concepts were then pooled to build the sub-corpus for evaluation.

**Manual annotation**

An annotation guideline was established for human experts to annotate all words that refer to a drug or a symptom, and then all words that refer to a drug or symptom whether there was a causal relationship between them in the context, without using any expert knowledge, experience or intuition to prejudge. Two pharmacovigilance experts with experience in ADR reporting, annotated blindly and independently a part of the sub-corpus. Both experts annotated a common part of the messages, which aims to estimate the inter-annotator agreement, to perfect the guidelines and to improve the quality of manual annotation. We then considered this manual annotation as Gold Standard.

**Comparison**

The basic metrics used to evaluate the performance are precision, recall and their harmonic mean (F-measure). Three different result types are examined: false negative (FN) for non recognition of relevant terms, false positives (FP) for irrelevant positive recognitions and true positive (TP) for correct positive recognitions. The precision, recall and F-measure are defined respectively as Eq.1,

\[
p = \frac{TP}{TP+FP}, \quad r = \frac{TP}{TP+FN}, \quad F_1 = \frac{2rp}{p+r} \tag{1}
\]

These statistics were computed globally and also specifically for each selected concept.

**Format and implementation**

The extracted forum messages were transformed in XML format for applying the STF Skill Cartridge. Automated annotations in XML format were parsed with R 3.3.1 xml2 packages. The sampling for sub-corpus constitution was carried out by building the list of message IDs with R and then integrating the corpus in the Skill Cartridge.

**Results**

**Description of dataset**

With the corpus described above,

- 55 777 entities of drug names from 34 265 messages have been annotated by the Skill Cartridge with thesaurus RacinePharma, which concern 1383 distinct drugs;
- 429 424 entities of symptoms from 153 995 messages have been annotated by the Skill Cartridge with thesaurus MedDRA, which concern 4861 distinct MedDRA terms.
- On the basis of drug and symptom recognitions, 1385 ADRs have been identified from 1129 messages.

Table 1 shows an overview of our dataset.

Table 1 – Dataset overview

The 12 drugs used for evaluation included four categories:

1. from the most frequent drugs in the corpus, PUREGON ( follitropin beta), SPASFON (phloroglucinol, trimethylphloroglucinol), and TARCEVA (erlotinib);
2. from the top 15 most sold in France, ASPIRINE (acetylsalicylic acid), LEVOTHYROX (levothyroxin), and DOLIPRANE (paracetamol/acetaminophen);
3. from the most interesting according to the pharmacovigilance experts: METHADONE, DIANE 35 (ethinylestradiol, cyproterone acetate) and PROZAC (fluoxetine);
For symptoms, the 3 most frequent PT selected were “anxiety”, “pain” and “fatigue”; the 3 of interest PT were identified in the MedDRA hierarchy makes it results are shown in Table 3. Although, we present in this comparison results

The sub-corpus for evaluating drug name recognition corresponds to 561 messages, in which the Skill Cartridge identified 721 occurrences of drugs corresponding to 27 distinct drugs. Table 2 shows the global scores and the scores obtained for each drug in terms of precision, recall, and F-measure.

For ADR identification, we evaluated all messages containing ADR annotation and obtained a precision 0.78, recall 0.63 and F-measure 0.70. Taking into account the great challenges of the processing of social media texts, this relation detection result is encouraging and promising for downstream analysis.

Discussion

In this paper, we have described a methodology by which text messages on social media can be effectively transformed into a usable format for pharmacovigilance. The protocol of evaluation, which includes a detailed sample size determination, has been highlighted, which is often obscure in previously published works. We have obtained a nearly perfect accuracy on recognition of drug names, and good performance on recognition of symptoms and ADR relations. It seems that some types of mentions or relation patterns are easier to extract than others. One of the key issues is still the informal narrative in social media containing many grammatical errors, abbreviations, spelling mistakes and lay terminology.

Our performance of recognition (F-measure 0.94 for drugs and 0.81 for symptoms) is comparable with other studies in the domain. In CHEMDNER BioCreative IV challenge [24], the chemical compound and drug name recognition task reached an F-measure of 0.88, while the disease named entity recognition reached an F-measure of 0.86 in BioCreative V challenge [25, 26]. With Electronic Health Records (EHRs) data, the F-measure of drug name recognition varies from 0.73 to 0.89 [27]. With social media, although various studies have attempted to adopt different methods to this specific text data source, there is still a gap on recognition performance due to informal and colloquial expressions. Most pilot studies of mining ADRs from social media [28-30] have investigated for English language, and the F-measure ranged from 0.58 to 0.82. The performance depends mainly on the size and quality of dataset. A study of detecting drug effects from a Spanish health forum has obtained a precision of 0.48 and recall of 0.59 [31]. In French language social media, a study of automatic identification of drug-related medical conditions on drug review [23] obtained a F-measure of 0.95 for chemicals, 0.86 for signs/symptoms and 0.82 for diseases, however the relations are not considered in this work. Moreover their corpus and evaluation set are much smaller than ours.

Even if the automated annotation of ADR relations is now restricted to the co-occurrence of drugs and symptoms in the same sentence, our human annotators were asked to annotate all ADRs in the post regardless of the sentence boundary, which allows us to further assess the impact of the sentence restriction and eventually improve the performance of detection of relations across sentence boundaries. The method of evaluation presented in this article contains potentially a bias of overestimation of recall. The false negatives are actually underestimated due to the fact that we worked with messages containing at least one annotation for one of the selected drugs, symptoms, or one annotation of ADR. Rational for choosing this approach is that half of the messages did not exhibit any entity of interest (neither drug nor symptom).

Next step will be applying signal detection methods within the pharmacovigilance database issued from French social media. A comparison of these potential ADR signals with those
detected from traditional reporting data will be performed. More work remains to examine how social media data can be incorporated into overall pharmacovigilance systems.

Conclusion

Our approach provides very encouraging preliminary results of recognition of drug names, symptoms, and ADRs in social media texts, which offer a promising basis for downstream analysis of routine or specific ADR signal detection.

Predicting Adverse Outcomes in Heart Failure Patients Using Different Frailty Status Measures

Abstract
Frailty is an important outcome predictor in older patients. We randomly sampled 12,000 veterans with heart failure diagnosed in 2010. The topic modeling method was applied to identify frailty-related topics from the clinical notes in the electronic medical records. The frailty topics were classified into five deficit areas including physical functioning (PF), role-physical (RP), general health (GH), social functioning (SF), and mental health (MH). We experimented with different covariates and four different frailty measures: individual frailty topics, number of distinct frailty topics, a dichotomous deficit category, and the number of distinct deficits, respectively. A total of 8,531 (71.1%) patients had at least one frailty topic. The prevalence of GH, PF, MH, SF, and RP deficits were 89.0%, 61.3%, 56.9%, 40.6%, and 9.5%, respectively. PF deficits (yes/no) and the number of distinct deficits were the most consistent, significant predictors of adverse outcomes of rehospitalization or death.

Keywords:
Medical Informatics; Frail Elderly

Introduction
Frailty commonly occurs in older adults and is an important determinant of health outcomes [3; 14; 16; 26]. Frailty is distinct from comorbidity and disease, and is a multifaceted combination of fatigue, weakness, malnutrition, and mobility [5, 15]. Frailty not only affects patients and caregivers, but is also a leading indicator of worsening health outcomes, including death. It is a barometer of how well patients may respond to treatment. However, frailty measurements are rarely collected in a quantitative, reliable fashion in routine patient care.

Frailty is specifically an important measure to assess cardiac peri-operative risk, morbidity, and mortality. Older patients with heart failure (HF) comprise a growing proportion of the cardiac surgery population. The Society for Thoracic (STS) risk model is often used to estimate risk, but includes no variables directly related to patient frailty [1]. Recently, smaller studies have demonstrated the added predictive value of frailty measures, for example the 5-minute gait speed [2] and a comprehensive frailty assessment [20]. Still, frailty is a key dimension that continues to be absent from quantitative risk prediction, in part because it is challenging to capture this metric on a large scale.

Fortunately, clinicians commonly document various aspects of frailty in clinical notes, especially when treatment plans change and/or when a patient’s quality of life is impacted, suggesting that perceptions of frailty is a component of clinician’s mental model of the patient’s status. The Department of Veteran Affairs (VA) national electronic health record (EHR) database is a particularly rich data source with an extremely large, older patient population with a comprehensive collection of different types of clinical notes.

In this study, we expanded on prior work examining the association between the number of frailty topics and adverse outcomes. We used existing frailty assessment instruments for ontological guidance, and created four different measures of frailty status to evaluate their role in predictive modeling.

Prior Work
In our prior work [19], we used a case control study design to estimate the association of the number of frailty with poor outcomes among HF patients. The outcome of interest was ≥2 hospitalizations following index HF hospitalization or death. A total of 709,389 notes were included from 12,000 patients. For training, we randomly selected 50,000 notes from 4,000 patients with the outcome, and 50,000 notes from 8,000 patients without the outcome. We ran the latent Dirichlet allocation (LDA) program from a java software package called MÄchine Learning and LanguageE Toolkit (MALLET), on the 100,000 notes, with the initial number of topics set to be 700.

To identify stable topics that were consistently present in different LDA runs, we first independently applied each of the 3 learned LDA models to the 709,389 notes using the topic inference tool included in MALLET. This step yielded 3 topic proportions per note for each note. Next, we defined a stable topic to be present in a note if at least 2 of the 3 topics in the topic triple corresponding to the stable topic had a proportion of 0.02 or higher in that note. This step produced 556 stable topics. An informatician and a physician independently reviewed all the stable topics and identified 53 topics that were related to frailty. The inter-rater agreement between reviewers measured by Kappa was found to be 0.818. We used the labels assigned by the informatics expert as human interpretations.

We discovered that increased number of frailty topics was statistically associated with increased risk of poor outcomes. Each additional frailty topic was associated with a 7% higher
risk of adverse outcomes. Compared to patients with <4 frailty topics, those with >=4 frailty topics had two times greater risk of developing an adverse outcome within 1 year following the initial HF diagnosis.

While the results were promising, further studies are needed because the area under ROC curve (AUC) was suboptimal in the prior work, at just above 0.6 regardless of the way we parameterized the frailty variable (coding it as a continuous or binary variable). This is partly because only a small number of covariates were used. However, when we included a larger number of covariates, the statistical significance of the number of frailty topics was diminished. Thus, more robust frailty measurements are needed to predict adverse outcomes.

Methods

Data Source

In this study, we used the Veterans Administration Informatics and Computing Infrastructure (VINCI) as the data source. VINCI contains comprehensive patient health and medical information from the US nationwide veterans’ EMR, which include both structured (i.e., race, gender, diagnosis code) and unstructured data (data in text documents, i.e., clinical notes).

Study Population

Patients in our study population were the same as those identified in the prior work [19]. They were 12,000 randomly sampled veterans with one International Classification of Disease 9th Clinical Modification (ICD-9-CM) HF diagnosis of 428.0-428.9 in 2010. They were composed of 4,000 veterans who experienced death or >=2 HF-caused hospitalizations during the year after the first HF diagnosis and 8,000 veterans who did not experience death and had at most 1 HF hospitalization during the year after first HF diagnosis.

Outcomes and Predictors

The main outcome of this study was defined as >=2 all-cause hospitalizations or death within 1 year after the first diagnosis of HF.

The predictors and covariates were identified from both structured and unstructured data. For the structured data, we used patient birthdate, gender, and ICD-9-CM diagnoses at each visit. Age was calculated as baseline age at the first diagnosis of HF. Patients’ comorbidities represented by ICD codes during the year before the first HF diagnosis were captured. The Charlson Comorbidity Index (CCI) was calculated based on these ICD codes via the methods described by Quan et al. [18].

For the unstructured data, we extracted topics from the Text Information Utility (TIU) notes. All the TIU notes dated within one year prior to the first HF diagnosis were extracted. Frailty indicators, which were not available in the structured data, were extracted from the TIU notes using the topic modeling technique.

Frailty Measurement Development

As described in the introduction section, we identified 53 frailty topics. Using these topics, we created four types of frailty measurements using the ontology knowledge from SF-36 and Frailty Index [23]. SF-36 and Frailty Index are commonly used among a number of frailty assessment instruments. We grouped the frailty topics into five deficit domains (called “deficits”), including physical functioning (PF), role-physical (RP), general health (GH), social functioning (SF), and mental health (MH). Topics relating to deficits in physical activities were grouped as PF; topics relating to deficits in role activities were grouped as RP; topics relating to general health perception or vitality (energy and fatigue) were grouped as GH; topics relating to deficits in social activity were grouped as SF; and topics relating to mental health were grouped as MH. The purpose of grouping is to see if some deficit domains are better than others to predict adverse outcome and if grouped deficits are more predictive than individual frailty topics. These comparisons are critical for developing frailty ontology in our future study. Since we are investigating how to measure frailty, each frailty topic and frailty deficit domain were first treated as individual variables. We then calculated an aggregate of the total number of distinct frailty topics and the total number of distinct deficits as additional variables.

Logistic Regression Models

We used logistic regression models to analyze the association of frailty and the outcome at the individual level. We assessed each of the four frailty measures (individual frailty topics, number of distinct frailty topics, deficit category, and number of distinct deficits, respectively) as predictors for the outcome. We also experimented with 4 different sets of covariates: set #1 including age, gender, and CCI; set #2 including age, gender, and individual comorbid conditions identified by ICD-9 diagnoses; set #3 including age, gender, individual comorbid conditions, and individual topics not related to frailty; and set #4 including all structured data (age, gender, CCI, ICD-9 diagnosis, Current Procedure Terminology [CPT] procedure codes, medications, and medical note type) and non-frailty topics. For each set of covariates, we built four logistic regression models separately with including one of four frailty measures in each model. Given the large number of comorbidity conditions and topics, we used automatic stepwise selection methods to set entry p-value at 0.2 and p-value at 0.05 to choose predictors other than the four frailty measures. A multi-linearity test was also conducted for each model to make sure there was no variable with variance inflation factor (VIF) higher than 10.

Results

Demographics

Among the studied cohort, 97.9% were males. The mean age was 69.7 (SD 12.1) years old, with 48.9% veterans aged 60-69, 26.1% aged 70-79, 21.9% aged 80-89, and 3.1% aged 90 or older. Just under a third of veterans (31.4%) had CCI of 0 (based on ICDs dated within one year of the first HF diagnosis) indicating no comorbid conditions, 34.3% veterans had CCI of 1-2, and 34.3% veterans had CCI of 3 or above.

Frailty Measurements and Prediction Models

Among the total 53 frailty topics, 22 were grouped as PF deficits, 19 as GH deficits, 7 as MH deficits, 4 as SF deficits, and one as a RF deficit. The grouping of frailty topics is described in Table 1. A total of 8,531 (71.1%) patients had at least one frailty topic in their medical notes, among which 89.0%, 61.3%, 56.9%, 40.6%, and 9.5% had frailty topics in GH, PF, MH, SF, and RP, respectively. As shown in Table 2 a-d, we created four sets of predictive models with each set using the same covariates and one of the four frailty measures as predictors, respectively. For each set of models, when the same covariates were used, the accuracy was very similar across the models, with AUC of 0.66, 0.80, 0.81, and 0.86 for set #1, #2, #3 and #4 of models, respectively.
Frailty Topics

Using individual frailty topics (rather than grouped into larger domains) sometimes resulted in a small (0.002 in AUC) improvement in prediction accuracy when compared with the other three frailty measures. As we included more covariates from set #1 to #4, the AUC improved from 0.66 to 0.87, regardless of what frailty measure we used. Including more covariates also caused fewer individual frailty topics to be significant (decreased from 12 in table 2 a to 2 in table 2 d). Most frailty topics did not consistently predict the outcome. The topic variable “503;383;345” was the only one that was always significantly associated with increased risk of outcome. This variable was a topic related to physical functioning with top 5 key words of “point patient assistance bathing independence.” This is because self-care activity is an important risk factor for hospitalization or death, which is not captured in ICDs.

Deficits

The number of distinct deficits was consistently associated with the outcome and the association was always significant except for the model including age, gender, and ICD covariates. Compared to the number of distinct frailty topics, the number of distinct deficits was more predictive and significant. The odds ratio estimate of 1.02 to 1.32 for the number of distinct deficits were consistently higher than the odds ratio estimate of 0.99 to 1.08 for the number of distinct frailty topics in each corresponding set of models. Among individual deficit variables, the PF was the only deficit that was consistently associated with increased risk of outcome. The GH was not predictive in any model; other deficits were significantly associated with the outcome occasionally depending on what covariates were included in the model.

When all structured data and other non-frailty topics were controlled, one additional deficit would increase risk of adverse outcomes by 6%. Although 6% seems small, the effect magnitude may be larger since the number of distinct deficits can go from 0 to 5. For example, compared to patients with 0 deficit, the risk of adverse outcomes would be increased by 12% and 34% among patients with 2 and 5 deficits, respectively.

Discussion

In this study, 71.1% veterans had at least one frailty topic in their medical notes. Since our cohort consisted of patients with HF, the prevalence of frailty was expected to be relatively higher than the general population. It also indicates the centrality of frailty in the mental models of cardiology. Our findings are congruent with other work in frailty. A review study found that the prevalence of frailty ranged from 15-74%, depending on the study population and method of assessment [22].

This study shows the importance of using ontological knowledge to aggregate frailty findings. Individual frailty topics and the number of distinct topics are not the best predictors, when compared to the burden from aggregated deficits. Frailty is an aggregation of deficits as others have noted. When using frailty topics as individual variables, most topics became insignificant, because of the lower prevalence and because frailty cannot be determined by a single finding. When aggregated, the impact of frailty became more pronounced. For example, patients with >=3 deficits had 1.16 times risk to have adverse outcomes compared with those with <3 deficits.

Conclusion

Frailty is not the only predictor of outcome. Depending on the covariates included in the models, the AUC ranged from 0.659-0.667 to 0.868-0.870. More covariates resulted in higher AUC, and once individual ICDs instead of CCI were included in the model, then AUC improved substantially. According to the generally accepted rule for AUC, models adjusting for set #1 covariates were inferior to good, since the AUC was less than 0.7 but higher than 0.5; models adjusting for set #2, #3, or #4 covariates were strong, since the AUC were around 0.8 or above [10].

Many studies have reported that frailty is independently associated with a higher risk of death and other adverse outcomes among people with cardiovascular disease or the elderly in both short term and long term [6; 8; 11; 13; 21]. These studies in general reported frailty prediction models with lower accuracy than ours, regardless of frailty measure methods. These studies also used many different instruments to measure frailty including frailty index, modified frailty index, frailty-related phenotype, frailty criteria, frailty survey, and frailty related signs and symptom scales, to predict adverse outcomes [4;7;9;24;25]. The AUC of these prediction models were in the range of 0.55-0.77, which was lower than those of our models [4; 7; 9; 24; 25].

Among all the deficits, physical functioning was the only persistent predictor of the outcomes. Frailty, however, goes beyond physical functioning. The number of distinct deficits was robustly significant even when we included many other predictors besides age, gender, and ICDs. These findings suggest that the physical deficits are possibly related to a generalized functional status latent variable and perhaps an indicator of the patient’s overall burden. Our finding fills a research gap in understanding what deficit of frailty topics and if increased number of deficits would be significantly associated with the higher risk of the adverse outcomes, which remained unknown in the previous studies [12; 17].

Our study has some limitations. First, we used the most commonly used HF ICD-9-CM codes to identify the study population, which might miss patients that should be included otherwise. Second, this study explored a simple ontology of frailty by classifying the frailty topics according to patients’ physical, mental, social function and general health status. Third, we set an equal weight for different deficits, which may not be optimal, since these deficits may have variable effect magnitudes on adverse outcomes. Fourth, in this study, we focused on the overall outcome, not the outcome following specific treatments, which might be more useful.

Our final goal is to create a more detailed ontology to improve the identification of deficits and guide the aggregation of deficits into meaningful frailty levels. In the future studies, we will conduct a survey among HF patients to identify deficits from their perspective. We will evaluate patients’ frailty levels following major cardiac procedures and examine the association between frailty level and time-to-events.

Conclusions

In summary, aggregate frailty deficit measurements created based on frailty topics and ontology knowledge significantly and strongly predicted adverse outcomes among heart failure patients.

Abstract

Epidemiological models are key tools in assessing intervention policies for population health management. Statistical models, fitted with survey or health system data, can be combined with lab and field studies to provide reliable predictions of future population-level disease dynamics distributions and the effects of interventions. All too often, however, the end result of epidemiological modeling and cost-effectiveness studies is in the form of a report or journal paper. These are inherently limited in their coverage of locations, policy options, and derived outcome measures.

Here, we describe a tool to support population health policy planning. The tool allows users to explore simulations of various policies, to view and compare interventions spanning multiple variables, time points, and locations. The design’s modular architecture, and data representation separate the modeling methods, the outcome measures calculations, and the visualizations, making each component easily replaceable. These advantages make it extremely versatile and suitable for multiple uses.

Keywords:
Computer-Assisted Decision Making; Statistical Models; Stochastic Processes

Introduction

An increasing number of epidemiological studies recognize that the front lines for tackling disease control and elimination are first and foremost policy and decision-making. Disease dynamics are heavily imprinted with uncertainty, complexity, and spatial heterogeneity [1-5]. This is particularly challenging for current strategies aimed at eliminating complex vector-borne diseases, such as malaria and lymphatic filariasis, which exhibit a high degree of geographic heterogeneity in infection patterns, and hence in transmission and extinction dynamics [6-9].

Indeed, previous works have shown that observed infection patterns display a high sensitivity to spatial and temporal factors. The dynamics of parasite transmission and extinction, as well as the intensity and duration of interventions, can vary significantly between communities owing to variations in initial ecological conditions [10-11].

Under these limitations, interventions must incorporate practices that effectively account for the variations in localized infection and control dynamics. This, in turn, underlines the need for new computational modeling tools. In contrast to previous models, which were based on the assumption of spatial constancy in rate parameters [12], the new models must support the elimination of diseases within diverse endemic settings.

A critical requirement for these tools is the development of an effective interface to help decision-makers understand the processes driving disease transmission and the effects of interventions in different settings. Such a system should also be able to assess the robustness of the conclusions derived from model simulations. Moreover, it should have the ability to visualize different control scenarios to aid effective policy evaluation in a spatial context. The policy evaluation process should assist in the task of simultaneously optimizing several incommensurable and competing objectives. For example, these may include the desire to minimize the time it takes to eradicate a disease, the number of people affected by the disease and by the interventions, the costs for the health system, and the costs for the population. Any solution would compromise a tradeoff between objectives, but some solutions may be better with respect to others.

We present a tool that couples observed and modeled data within an interactive visualization environment. The tool enables policy makers to analyze and interpret outputs of simulations, map and identify areas with persistent infection, and run scenarios to evaluate the application of spatially variable intervention options to disrupt transmission reliably everywhere.

Our tool’s aim is to allow policy planners to explore and compare simulated policies through a consumable interface that simplifies the presentation of spatio-temporal data under different intervention scenarios. The tool allows practical comparison of policies effect, and is easily customizable to specific regions or locations, time frames, and models.

Methods

Web Application Implementation

The tool is a web application that follows the standard Model View Controller (MVC) design pattern. We implemented the tool’s front-end in HTML5 and JavaScript using jQuery (https://jquery.com/) and AngularJS (https://angularjs.org/). For visualization purposes, we used the following libraries: Bootstrap (http://getbootstrap.com/), D3 (https://d3js.org/), Leaflet (http://leafletjs.com/), and IBM’s time-oriented visual analytics kit (see below), which was developed by our team. The server side was implemented in Python using the Flask web framework (http://flask.pocoo.org/). The database is
The visual analytics kit is a general-purpose visualization tool that is tailored to the analysis of time-series data by data scientists in healthcare. It is a JavaScript library that was developed separately from the tool described in this work [13] and is used here to display time series charts. Its primary goal is to shorten the time it takes to visualize and gain insights from data, without necessarily requiring knowledge in programming or in visualization per se. Users of the kit can create interactive charts and views of their data with a convenient declarative interface. In addition to the native JavaScript webpage integration capability, the library has interfaces for several different languages such as R, SAS, and Python, and can be used within Jupyter notebooks to display interactive figures. Among the available charts, users can find timelines, flow-charts, and matrix-views for many different tasks and purposes.

The focus of all of the kit’s charts is the assessment of the temporal aspects of the data. Different structures of time are supported by appropriate views. In our tool, we used the linear time line structure, which can reveal trends and tendencies. Support of cyclic and calendric views is currently under development.

The kit was developed with a view that interactivity is key in visual knowledge discovery. The kit therefore supports brush, pen-and-zoom, and all mouse events out of the box. Our app makes use of the mouse events and programmatic interface to link the kit’s time-series views with a map-based choropleth view (described below). Users can create a temporal alignment of event sequences to a common event or index date. Detection of patterns can be aided by performing temporal aggregation and noise reduction that can be applied or removed on the client side, without the need for resending of data, which can be time and bandwidth consuming.

Data Content

The tool receives location demarcation information in GeoJSON format, a geospatial data structure based on JavaScript Object Notation (JSON). In our demo, we use GeoJSON files representing Africa’s countries and provinces, downloaded from Natural Earth (http://www.naturalearthdata.com/). Average temperature/rainfall of the period 1990 to 2012 was taken from The World Bank Climate Change Knowledge Portal (http://sdwebx.worldbank.org/climateportal/).

Generating Policy Dependent Simulations

Any framework can be used to drive the generation of scenario simulations for the tool, as long as it provides results that can be described as numeric variable values that are specific to policy, location, and time (in the required JSON format). Figure 1 describes a general framework for learning models from data and generating forecasts under multiple intervention policies. The models are fitted by statistical machine learning software using model specifications and data to produce learned (possibly location-specific) model parameters. The simulations are created by model simulators using fitted models in conjunction with existing data and specified intervention (policy) specifications. The simulations are then evaluated using evaluation modules that take the scenario simulation results and process them using the specifications of the evaluation measures and, possibly, cost specifications provided by modelers to produce predicted outcomes (objective values). The policy-planning-related results of the whole process are visualized in the decision support tool.

To demonstrate the decision support tool, we constructed a weather-dependent generative malaria model. The exact details of the modeling work are not important to this report; they are not based on actual disease prevalence measurement data and therefore not meant to provide true estimates of malaria for the respective countries. Here is a high-level description to illustrate the complexity and richness of the dynamics involved:

We modeled the epidemic as a vector-host-weather model. State variables included temperature and precipitation (driven by annual mean + integrated fluctuations), Susceptible, Exposed, Infected and Recovered (SEIRS) proportions of humans in the population, and Susceptible, Exposed and Infected (SEI) number of mosquitoes per human.

We modeled the dynamics by a set of Ordinary Differential Equations (ODEs), integrated using the Euler method with constant time step size and state dependent noise.

The model parameters that are determined by temperature and precipitation affect the dynamics of all other state variables included adult mosquito birth rate, adult mosquito per capita death rate, mosquito biting rate, proportion of bites by susceptible mosquitoes on infected humans that produce infection, duration of the sporogonic cycle, survival probability of infected mosquitoes over the incubation period of the parasite, and proportion of bites by infectious mosquitoes on susceptible humans that produce infection. A similar model was previously presented by Parham and Michael [10].

The modeled intervention options included the presence of Insecticide Treated bed-Nets (ITN) and Indoor Residual Spraying (IRS) for specified proportions of the human population. Their effects are somewhat different; ITN prevents bites but does not affect the size of the mosquito population, while IRS both prevents bites and slightly affects the mosquito death rates. ITN and IRS began at a value of zero in all policies and changed to a policy-determined fixed-value at the end of the
second year. Other patterns could have been applied (e.g.,
degradation effects).

Results

Policy Selection and Comparison

The first tab of the system displays the details of all available
policies in separate panels (Figure 2). Each panel consists of
the policy’s title, a short description, and its cost and length
parameters. The left pane enables policy filtering by the same
parameters. The user may also select specific policies of inter-
est and the tool will produce a comparison table for them. Ex-
cept for policy title and description, the appearance of all other
fields is configurable.

Co-Representation of Spatial and Temporal Data

Each policy may be opened in a separate Scenario Explorer
tab, where users can observe its effect in both time and space
(Figure 3). The left pane is dedicated to visualizing temporal
data for a selected country. The user may select which of the
available charts should be visible and the desired time range.
Each chart shows measurement (e.g., survey) data when avail-
able and model-generated estimates comprising the median
value as well as a confidence interval. Hovering over a chart’s
line displays the median value and date at that time point;
clicking on it modifies the display on the map to the right.

When a time point is clicked, the map’s colors change to a
choropleth, which shows the value of the selected chart and
time point for each of the modeled regions. For example, the
map in Figure 3 is colored by precipitation values on January
1, 2017. The selection of chart and time point also opens two
legends: one shows the value range matching each color, and
the other shows the values of all charts in this time point for
the selected region. Hovering over different regions at this
stage will change the latter to display the hovered region’s
current charts’ values. Selecting a new region will load its
time series data in the left pane, without changing the charts
selected to be visible or the time range.

The user can add more policy Scenario Explorer tabs to pre-
sent while preserving the configuration from previous ones.
The tabs are synchronized so that selecting a region or a visi-
ble chart, setting the time range, or selecting a time point on a
specific chart, updates all other policy tabs to show the same
properties for their respective policies. As such, the user can
make personalized configurations on one of the policy tabs,
and then easily compare the outcomes of other policies by
simply switching between tabs.

![Figure 2 – Policies Selection tab. Each panel represents a
single policy. Policies may be compared in a table or by opening
those of interest in ‘Scenario Explorer’ tabs. The left pane
enables policy filtering by cost, length, and intervention types.](image)

![Figure 3 – Scenario Explorer tab. The left pane shows the
data as time series charts for a specific country (Ghana). The
right pane shows the data as a choropleth map of all African
countries for a specific time point (01/01/17).](image)

Proof of Concept: The Malaria Case

In order to demonstrate the tool’s capabilities, we present a
use case for malaria intervention in Africa. The model de-
scribed in the methods was used to obtain malaria prevalence
estimates for African countries for four ITN and IRS policies.

We obtained initial simulation values by running the simula-
tion forward from a random initial condition for several annu-
al cycles. The results differ across regions due to the differ-
ences in annual mean weather conditions, and across policies
due to differences in the application and amount of IRS and
ITN. For the purpose of this work, we generated four policies:
with no intervention, with ITN at 30% and IRS at 20% from
year 2, with ITN only at 50% from year 2, and with IRS only
at 60% from year 2. For each location, 2000 simulation runs
were conducted and the median, 25 and 75 percentiles were
calculated per time point to extract inputs for the tool. Since
malaria prevalence is seasonal, we extracted the mean preva-
ience in a running yearlong time window as a policy perfor-
ance measure. The results of this measure are shown in Fig-
ure 4 for Ghana.

As can be seen, the mean prevalence differs across policies in
the size of the median effect and in the variance of the predict-
ed distribution. In the presented view, it is clear that the model
predicts 60% IRS (Figure 4d) to be more effective in Ghana
than the other policies, both in terms of reducing the median
and in terms of minimizing variability of the measure. In a real
policy decision support scenario, other performance measures
such as policy costs would be taken into consideration in a
multiple goal optimization setting. In this demo-scenario, the
policy would present a tradeoff between policy effectiveness
and costs shown in Figure 2, such that no one policy outper-
forms across both measures.

A Single Flexible Framework for Multiple Scenarios

The system can be easily adapted for multiple purposes, as it
relies only on a few configuration files, and the data itself is
held in structured files: The map polygons are generated from
GeoJSON files (see Methods), meaning the countries display
can be easily switched to display different geographical re-
regions (e.g., states, provinces or even houses) by providing the relevant set of files. Model results can be of any type supported by the time-oriented data visualization library and only need to match the geographical entities (see Methods). The policies are held in JSON files, as are the data by region and by time point for each policy. These files were uploaded to a NoSQL document-based database (see Methods), and as such have a flexible structure that can be easily edited or automatically generated (see Technical Appendix).

Thus, supporting different diseases, policies, or chart types, as well as results from entirely different domains is possible and requires minimal effort.

Second, DHIS2 is not geared towards visualizing or comparing prediction data for multiple what-if scenarios, and does not measure or estimate distributions for a specific location and time. Thus, the ability to use this tool for future policy planning is limited. DHIS2 is, however, open source, modular, and highly extendable. Plans for future development include DHIS2 integration that will enable using our tool to visualize results and select policies, and then transfer selected policy prediction results back into DHIS2 so that they can be shared with the numerous users of that system.

Our tool was implemented in a manner that allows complete domain flexibility. It does not rely on specific types of data or regions. Any measurement and modeling results of a spatio-temporal nature, and any numeric calculated outcome measures can be visualized. Policies are defined by the types and values of intervention parameters and can be compared by any of the parameters or supplied (model generated) time dependent variables. The number of charts and their types can be easily configured, as well as the area of concern and its division into comparable regions.

With that said, the system still has some limitations. Its performance is linearly dependent on the number of charts, the number of time points, and the number of displayed policies. It is responsive to touch-screen interfaces (mobile devices), though the full map and charts view is better displayed on larger screens. Lastly, the actual modeling and the interface that runs the models to produce policy a prediction is currently separate from the tool. While this allows for greater flexibility in selecting modeling environments, future work will integrate the specification of policies and consequent running of models into the web-based interface.

Conclusions

We describe a novel tool for policy planning and decision support over spatial and temporal data. It offers visualization for the multi-dimensional effects of different policies, simultaneously across different regions and different time ranges. The tool, which focuses on user interaction and visualization, is, by design, separate from the modeling and simulation framework; this allows it to serve a wide range of models and modeling choices. Although we chose to demonstrate its abilities for the analysis of epidemiological data, it can be easily used for decision support in other spatio-temporal domains (e.g., agriculture). Models of infectious diseases and, especially, vector-borne diseases can be quite complex. Similarly, policy objectives can be numerous and their focus can span multiple time periods. Therefore, choosing the best policy involves not only accurate modeling, but also using tools that allow policy makers to view and explore complex statistical spatio-temporal information in a manner that is easy to digest.

Technical Appendix

Our database server is document-oriented. Each entity – in this case: policy, region, time point – is defined as a type within a JSON file, while all JSON files are held in the database and are stored in an optimized key-value paradigm. The JSON files formats divide into three types accordingly:

- Policy (Figure 5; top) – uniquely describes a single policy, including all the interventions implemented as a part of it
• Time point (Figure 5; middle) – contains the values of all regions on all charts in a single time point, under the policy defined in “policy_id”

• Region (Figure 5; bottom) – contains the values of all time points on all charts for a single region, under the policy in “policy_id”

The Pluripotent Rendering of Clinical Data for Precision Medicine

Christopher G. Chute¹, Stanley M. Huff²

¹ Chief Research Information Officer, Johns Hopkins Medicine, Baltimore, MD, USA,
² Chief Medical Informatics Officer, Intermountain Healthcare, Murray, Utah, USA

Abstract

Health care and biomedical research are awash in data. Traditional data warehouse methodologies do not scale to this challenge: nor do their schema match the variety of analytic use cases. An alternative model, which shreds data into well-formed constituent data elements, conformant with the emerging CIMI-FHIR standards and stored together with the complete, raw, source data using modern and scalable data utilities such as Hadoop and its derivatives, affords the creation of pluripotent data repositories. Such repositories can be leveraged to generate any number of data marts, registries, and analytic data sets, each of which “just in time” binds an appropriate use-case specific data model. We call this notion PiCaRD: Pluripotent Clinical Repository of Data. We believe such nimble biomedical data management strategies are crucial for Precision Medicine discovery and application.

Keywords:
Archiving; Reference Standards; Common Data Elements.

Introduction - The Data Challenge

Health care and biomedical research have become profoundly information intensive [1]. It is inconceivable today to practice “best evidence” medicine without the monitoring of practice pathways, potential adverse events, and increasingly, genomic correlations. The depth and breadth of pertinent information long ago outstripped the capacity of humans to know and understand the full spectrum of pertinent knowledge, never mind to accurately and reliably recall all that should be considered. From an analytic perspective, we are seeing the aggregation of data, such as health claims at national scale, with the integration of data arising from electronic health records (EHRs) and their supporting systems, such as detailed departmental sources, diagnostic devices, ‘omics repositories, PACTS, and ICU waveforms. Perhaps most significantly, it has become self-evident that within five years, a far greater amount of clinically relevant data about our patients will be generated outside of the healthcare delivery industry than within it. Specifically, the proliferation of smart-phone and home monitoring devices, tied wirelessly into personal health networks, is starting to generate continuous waveform monitoring of pulse, blood pressure, respiratory rate, blood glucose, patient activity, location, ambient light, other environmental exposures, and sleep quality, to name but a few examples. Image data is capturing detailed diet information, risk behaviors, occupational hazards, and living conditions.

Traditional methods for managing these tsunami of detailed, heterogeneous, and complex data will not scale to the emergent challenges of discovery research, population health management, continuous quality improvement, comparative effectiveness analyses, patient centered outcomes research or operations research. We propose a re-thinking of how health systems regard health-related data, curate it for inferencing and discovery, and engage in information partnerships with their populations and patients.

Precision Medicine

The advent of Precision Medicine poses additional demands on data access. Based on the principle that detailed knowledge of a patient can precisely inform optimal treatments and interventions, the idea relies on access to vast clinical information resources that can inform these decisions. During the process of assembling such data resources, the problems of large data volume, heterogeneous semantics and syntax, and disconnect data schema all present challenges.

Several countries have engaged in large-scale population studies, collecting rich datasets of many data types including clinical, genomic, and mobile-device generated data. The United States, through its Precision Medicine Initiative [2], now rebranded as the “All of Us” project [3], will generate datasets that exemplify the challenges outlined above. We are posing our solution to address these and related datasets that can enable facile analytics for Precision Medicine.

Traditional Data Repositories

Most health systems consider the information about their patients to be contained in their administrative systems and their EHRs. Yet healthcare delivery in the US is palpably fragmented, with information about patients distributed among many EHRs for any given patient to the extent that it measurably distorts phenotyping and analytics [4]. Internally, departmental and diagnostic systems generate huge volumes of data, only the veneer of which typically is transferred to EHRs and which is almost always stripped of its metadata and provenance. For example, ECG tracings are typically reduced to static images with reporting parameters, generated by stand-alone machines. ICU’s and floor monitors generate highly detailed waveform data, which are either discarded outright or collapsed into quantitative snapshots such as blood pressure, oxygen saturation, temperature, and related physiological measurements. Again, the untapped potential in these waveform data offers demonstrable contributions to our understanding and management of many disease manifestations [5].

Most clinical data warehouses are a derivative of the EHR, and thus suffer from all the lossy transforms and metadata pruning that occurs. While such data reduction may be
judicious for the acute management of most patients, the
information loss cannot but compromise deeper data analyses,
association finding, and metric development to deliver better
care. Finally, while Meaningful Use [6] is mitigating the data
comparability and consistency challenge in the United States,
multicenter research and networks such as CTSA and PCORI
still confront the reality that most data repositories reflect the
idiosyncrasies of localized and divergent coding systems, data
models, and renderings that seem to remain the birthright of
every healthcare delivery organization. Much of this data can
be and often is translated into a canonical representation,
though the perennial question of what constitutes the
canonical information standard is debated across interest
groups, standards development organizations, and analysts.

Relational Systems

The pioneering work of Edgar Codd on relational algebra and
set theory in the 1960s and the subsequent development of
relational databases [7] has dominated the database world for
decades. Most database implementations invoke the relational
model and the by now truly standard Standard Query
Language (SQL). These are enormously efficient data
structures to answer questions when the query design is
known; however, when queries imply a different schema, they
can be unworkably non-performant. For example, most EHRs
organize data by patient, which means that a query across all
patients can be inefficient, if not unmanageable. Clinical and
translational research, by their nature, encounter questions that
cannot be anticipated in any given data structure. For research
retrieval many have stated, “all schema are wrong.” For this
reason, alternatives to SQL data structures are increasingly
emergent for research queries, though clinical data repositories
have not yet widely adopted those structures.

Scalable Data Structures

The emergence of Not Only SQL databases (NOSQL), such as
Mongo and Couch DB, have relaxed the constraints of
relational schema with only minimal impact on retrieval
efficiency. Most such databases are document-centric, where
the information is stored as an annotated document, aligning
with an XML data definition or schema. An alternative is the
entity-attribute-value structure, manifest in the MUMPS
architecture as perhaps one of the original NOSQL data
structures.

The advent in the 1980s of big-data management
environments, orthogonal to the nearly coincident emergence
of practical relational databases, has spawned what many
regard as a notable, fundamental shift in computing, generally
classified under Stonebraker’s influential “shared nothing
architectures” [8] and initially popularized by companies such
as Tandem and Teradata. This architectural design supports
nearly infinite scaling, because the independent and self-
sufficient component parts of the system “share nothing,” such
as file systems or memory, with the others. Apache Hadoop
[9] is a relatively recent open-source project implementing
“share nothing” design, thus allowing for the distributed
processing of large datasets across clusters of computers. The
suitability of Hadoop and its derivatives for clinical and -omic
data has been previously described [10].

Self-describing Data Objects

The tension between chaotic data heaps (no schema) and
constraints on data expression and retrieval (relational schema)
suggests an optimal point in the middle, a just-right
Goldilocks level of schema. Clinical Information Modeling
Initiative (CIMI) [11] data element objects are designed to be
that optimal level of structure, ensuring data coherency and
interpretability without imposing premature binding on data
relationships and structure. Nevertheless, the opportunity to
create relational or other schema, a late-binding approach, is
preserved through metadata and provenance information
carried along with the clinical data element object. CIMI data
elements can be regarded as a more fully specified rendering
of FHIR [12] resources, with which CIMI maintains close
alliance.

The payload of any data object may be misinterpreted if the
context and provenance of the data collection are missing.
Thus crucial to clinical data element interpretation and
filtering is the metadata, including date times, workflow
context, and key relationships to other data objects (such as a
drug-level test explicitly related to a drug order). Additionally, a cache of the raw, untransformed data should
always be stored as part of the data element object, to enable
retransformation or correction of the normalized CIMI-based
rendering.

Pluripotent Data Repository

What we are proposing and promoting is a “next generation”
clinical data repository framework, premised on a collection
of pluripotent clinical data elements, which we call PiCaRD:
Pluripotent Clinical Repository of Data. These data elements
are managed in modern “share nothing” data architecture.
data into a common framework. The careful preservation of complete, raw source data in parallel protects against incomplete preservation of data in any particular canonical form, and secular change in the normalized specification. Correspondingly, that framework would sustain federated inquiry across different organizations, assuming appropriate consent and authorization were in place.

**Derivative Data Marts, Registries, and Analytic Datasets**

The resulting “data soup” (a data lake full of self-describing data objects), replete with bulky data elements, is likely to be a suboptimal environment for analytic inferencing and report generation. However, such a pluripotent repository can generate an arbitrary number of derivative data marts, registries, and analytic datasets on demand or periodically. These derivative data collections can be bound to an appropriate data schema or relational model, where iterative reporting and inferencing can proceed efficiently. This concept of “late binding” to a data schema optimized for the data-collection use case is critically important. For example, one could generate an arbitrary number or variations of i2b2, OMOP, OHDSI, or the PCORI CDM, illustrating late binding. The normalized repository comprises a hub, in a hub and spoke configuration, contrasting with the point-to-point configuration in Figure 1.

**Precision Medicine Application**

The recent announcement that the US Precision Medicine Initiative (PMI) will use FHIR interfaces to enable patients to forward clinical information to the coordinating center is a strong advocacy for using FHIR structures for PMI discovery research. Specifically the *Sync for Science* toolkit [18] being developed for the harvesting of clinical data by patients in the PMI is based upon the FHIR specification. Over time, this will enormously simplify data upload into a PiCaRD repository, as many of the normalizations steps will be unnecessary in the face of native FHIR data object transfer from *Sync for Science*.

**Conclusion**

Historical data warehouse designs, while addressing many practical needs, are unlikely to scale to the scopes demanded by health systems in this information-intensive age. A more nimble framework, invoking data schema and structure only at the level of a clinical data element, can demonstrably capture an unbounded number of raw and processed data types. Using current “share nothing” data models such as Hadoop derivatives, it can also perform effectively in big data problems. Such a resource can in turn generate an arbitrary number of data marts, registries, and analytic data sets, each of which can manifest use-case specific optimizations of schema and data models. This pluripotent data framework will not displace traditional data warehouses but can be the foundation on which purpose-specific data warehouses can be efficiently generated and maintained.

Classification of Clinical Research Study Eligibility Criteria to Support Multi-Stage Cohort Identification Using Clinical Data Repositories

Abstract

One of the challenges to using electronic health record (EHR) repositories for research is the difficulty mapping study subject eligibility criteria to the query capabilities of the repository. We sought to characterize criteria as “easy” (searchable in a typical repository), “hard” (requiring manual review of the record data), and “impossible” (not typically available in EHR repositories). We obtained 292 criteria from 20 studies available from ClinicalTrials.gov and rated them according to our three types, plus a fourth “mixed” type. We had good agreement among three independent reviewers and chose 274 criteria that were characterized by single types for further analysis. The resulting analysis showed typical features of criteria that do and don’t map to repositories. We propose that these features be used to guide researchers in specifying eligibility criteria to improve development of enrollment workflow, including the definition of EHR repository queries for self-service or analyst-mediated retrievals.

Keywords: Informatics, Biomedical Research, Electronic Health Records

Introduction

While paper-based patient health records have a long history of being used to identify potential research study subjects, the advent of electronic health records (EHRs) has greatly facilitated researchers’ access to relevant patient data, especially when they are transferred to data repositories or warehouses specifically designed for this purpose.[1] Researchers may use such information for estimating the availability of eligible research subjects in some larger target population (cohort estimation), identifying specific patients who might be interested in enrolling in a research study (cohort identification), or trying to guide researchers in specifying eligibility criteria to improve development of enrollment workflow, including the definition of EHR repository queries for self-service or analyst-mediated retrievals.

We believe that this multi-step process can be facilitated by characterizing eligibility criteria in advance as either being amenable to retrieval with repository tools (“Easy”) or requiring some more elaborate mechanism (“Hard”). If a researcher specifies criteria in this way in their research protocols, the task of the repository user can then be reduced to a feasible retrieval step to identify an initial cohort that is then passed on to the next stage in the process for application of additional criteria through other means. The purpose of the study presented here was to explore the characterization of eligibility criteria to determine if such an approach is feasible.
Methods

We obtained the ClinicalTrials.gov (NCT) identifiers (a US registry of clinical trials that includes enrollment criteria) for a convenience sample of 10 studies conducted at UAB that were chosen for a separate study of the use of EHR data for cohort prediction (unpublished data). We then incremented each NCT ID successively until it matched an additional study. For example, the NCT ID NCT01098981 would be incremented to NCT01098994 to find the additional study. These twenty studies provided eligibility criteria that served as the data set for our study. The NCT record for each study was examined to identify eligibility criteria (see, for example, https://clinicaltrials.gov/ct2/show/NCT01098981) which were copied from a Web browser screen to a spreadsheet.

The authors of this study served as experts for rating the eligibility criteria. JJC was the principle architect of the National Institutes of Health’s Biomedical Translational Research Information System (BTRIS)[8] and has extensive experience with its use for matching patients to research criteria.[9-12] WJL was a medical resident University of Alabama School of Medicine (UASOM) at the time of the study, with extensive experience with electronic health records and moderate experience with UASOM’s i2b2 (Informatics for Integrating Biology to the Bedside)[13] repository. MCW is a systems analyst, with responsibility for, and experience using both i2b2 and PowerInsight (Cerner Corporation, Kansas City, MO), the clinical data warehouse attached to the EHR used by UASOM.

Each of the authors reviewed the resulting criteria and rated them with a scale (shown in Figure 1) that was intended to capture the rater’s judgement as to whether a typical clinical data repository, such as i2b2, BTRIS or PowerInsight, would be able to identify subjects meeting the criterion based on information available in a typical EHR. Raters were permitted to assign multiple scores in cases where a “single” criterion actually included multiple clinical concepts. The ratings were compiled and summarized to determine the characteristics of criteria that could be readily used with EHR repositories, versus those that could not.

Results

Criteria Data Set: A sample of the clinical trials used in this study are listed in Table 1. The cleaning process yielded a set of 301 criteria, of which 292 were found to be exactly or essentially unique each of which was rated by each rater (876 ratings in all). Examples are shown in Table 2.

Criteria Ratings: In 29 of the 876 ratings (3.3%), involving 18 of the 292 criteria (6%), reviewers found some difficulty assigning a single code to a complex criterion (see Table 2). When these 18 criteria were excluded from further analysis, all three raters agreed on the same rating 140 times for the remaining 274 criteria (50.9%), with least two of three raters agreeing 256 times (93.1%). Three raters agreed or one rater differed from the other two raters by one (for example, two said “1”, and the third said “2”) on 244 (89.1%) of the criteria. Agreement between pairs of raters ranged from 66.5 to 66.9%, with Pearson’s Correlations between .7901 and .8178 (p<.00001 for all comparisons). Table 2 shows examples of ratings and Tables 3 and 4 summarize the intrarater statistics.

Characteristics of Easy Criteria: Raters had unanimous or nearly unanimous agreement that 80 criteria were “easy” (with complete agreement in 85% of cases). In general, these were related to the categories of data that are provided by repositories like i2b2 and BTRIS, such as laboratory results, vital signs, diagnoses, procedures and allergies. The raters were undaunted by criteria that included temporal restrictions such as “digoxin within 6 months of starting treatment” and “parathyroidectomy within 12 weeks prior to screening”. In addition, criteria involving complex phenotypes were considered “easy” if they could be addressed through an assemblage of individual easy criteria.

Characteristics of Mixed Criteria: Raters had agreement or near agreement that 70 criteria were “mixed” (with 47% in complete agreement), that is, the criterion could be partly retrieved using the repository’s user interface but then would require further manual review. These criteria generally included some mention of an “easy” criterion, coupled with some restriction or co-occurring state or procedure that either was not itself an easy criterion or the relationship between the two could only be carried out by a manual review.

Characteristics of Hard Criteria: Raters had agreement or near agreement that 50 criteria were “hard” (with 70% in complete agreement), that is, matching the criterion would require manual review of the record. These criteria span the breadth of EHR findings that typically appear in physicians’ notes and procedure reports. Some were parts of “mixed” criteria, such as “females who are breastfeeding”. Others are statements of patient condition that would not be reflected in a typical problem list, such as “prisoner”. Scale-based assessments, such as “Pre-morbid modified Rankin score of 0-1” were common. Finally, some criteria might require the researcher to use the clinical record to make the assessment, such as “Candidate for phototherapy or systemic therapy”.

Characteristics of Impossible Criteria: Raters had agreement or near agreement that 44 criteria were “impossible”, that is, the repository would not be likely to include sufficient information to match patients to the criterion. Complete agreement occurred in only 24 cases (55%). While some of the “impossible” criteria related to the time factor of the data (such as “Parents/children who refuse to participate in the study” and “presenting within timeframe for intravenous tPA treatment approved by local regulatory authorities but no more than 4.5 hours from onset of symptoms”), other cases depended on raters’ opinions about which relevant data simply do not find their way into EHRs, such as “Facial Hair”, “good health”, and “Able to swallow tablets”.

General Recommendations: The data presented above can be summarized by separating out “easy”, “hard” and “impossible” criteria into explicit lists (see Figure 2). This list, in turn, can be used by those developing eligibility criteria such that they can anticipate the workflow needed to identify potential research subjects using repository query tools, manual record review, and real-time interventions at recruitment sites.

Criterion is likely to be easy to retrieve from an EHR repository if:
they correspond to simple data types (e.g., laboratory, medications, diagnoses, procedures, vital signs) they have simple temporal restrictions (start or stop dates, but not before or after other events) phenotypes that can be completely described by the above criteria

Criterion is likely to be hard to retrieve from an EHR repository if:
a restriction is placed on a simple criteria, such as severity, location or treatment status of a condition. a calculation based on simple criteria the finding is reported as a rating on a standardized scale it requires information that would be likely to appear in the text of a clinician’s note or procedure report a researcher’s judgement is needed regarding suitability, based on information in the record

Criterion is likely to be impossible to retrieve from an EHR repository if:
it is not typically captured in EHRs it must occur close to the time of enrollment it can only be determined during enrollment (such as willingness to undertake or forego some activity)

Figure 2 - Features that suggest they will be easy, hard or impossible to retrieve from a typical EHR
Discussion

The use of EHR data for research is a rapidly evolving phenomenon. The development of methods for “large pragmatic trials” is, in particular, reliant on EHRs.[14] Yet the methods for defining eligibility criteria remain largely unchanged in practice, with little apparent attention paid to the fact that the criteria elicited from a patient filling out a questionnaire might differ in fundamental ways from those elicited from an EHR.

A great deal of informatics research has examined the semantics of clinical research eligibility criteria. Projects such as the Ontology of Clinical Research (OCRe),[15] and the Agreement on Standardized Protocol Inclusion Requirements for Eligibility (ASPIRE)[16] have defined broad classes of criteria (such as demographics, disease-specific features, functional status, etc.) with the intent of making them computable for comparison across studies. The semantic complexity of these classes of criteria has been studied in depth by Ross and colleagues.[17] Weng and colleagues provide a comprehensive review of this work[18] and extended it with detailed analyses of the semantic types of criteria,[19] including the use of the National Library of Medicine’s Unified Medical Language System[20] and NIH’s Common Data Elements.[21] To our knowledge, however, there have been no systematic studies of how such criteria translate operationally to what can and can’t be accomplished with EHR repository query tools.[2-4]

We did not set out to create a reusable criteria rating scale, but rather sought to simply find a specific set of criteria that could be used for further analysis. Nevertheless, we experienced fairly good interrater correlation in the use of our scale. Although this study was carried out by one set of researchers at one institution, we are of diverse backgrounds (medicine, informatics, and information systems) and draw on experience with three very different repositories (Power Insight, i2b2 and BTRIS). Examples of criteria on which we agreed and disagreed are included in Table 2 for the reader to judge whether our rating method appears generalizable.

Our examination of a randomly collected set of enrollment criteria suggests that a large percentage (at least 89%) can be readily classified as easy, hard or impossible to retrieve from EHR data repositories. We do not make any claims, given our sample size and sampling method, about the actual ratios between easy, hard and impossible criteria across the spectrum of clinical trials. But, it seems logical to take advantage of the knowledge that such distinctions exist for developing the methods to be used for matching patients to criteria when EHR data repositories are being used for at least a part of the process. It should not be hard to imagine an interactive “wizard” that queries researchers for criteria in structured ways that ask first for easy elements that can be addressed with a repository search tool:

- What calculation would you like performed on the previously specified laboratory test result?
- What should the indication for the previously specified medication be?
- What findings should be present in, or absent from, the text report for the previously requested procedure?
- What complex phenotypic pattern should the patient have?

It could then move on to elements that can only be ascertained at the time of enrollment:

- What acute event will the otherwise eligible patient have (or not have) at the time of presentation?
- What will the patient have to agree to do (or not do) in order to be eligible for enrollment?

This hypothetical wizard might then produce a coherent set of eligibility criteria that could specify a multi-staged enrollment process that starts with a set of data queries, proceeds to manual review of full records, and then specifies what additional information will be needed on specific potential subjects through direct contact, perhaps by flagging them in an EHR’s alerting system to notify the researcher when they appear in a patient care setting.[7]

The findings of our study are only a building block in the development of an approach to improve the specification of eligibility criteria. An understanding of the pragmatics of interfacing with actual clinical data repositories can inform previous work on the semantics and interoperability of criteria. A set of questions, such as those listed above, guided by knowledge of criteria semantics, would help to establish a dialogue between the investigator and the data analyst (or provide an opportunity for introspection if the investigator is using a repository in a self-service mode). Further improvement would likely require an iterative process of extensions, corrections and refinements.

Conclusions

The findings of this study support the hypothesis that clinical research eligibility criteria fall into stereotypical categories with respect to data available in EHR repositories. By describing these categories explicitly, the possibility exists that a structured process, perhaps using a data entry form or interactive “wizard”, could be developed that would allow researchers to express their criteria in ways that would allow establishing realistic expectations for the recruitment process and improve retrieval of data, either by analysts or the researcher herself.

Abstract

Prior knowledge of the distributional characteristics of linguistic phenomena can be useful for a variety of language processing tasks. This paper describes the distribution of negation in two types of biomedical texts: scientific journal articles and progress notes. Two types of negation are examined: explicit negation at the syntactic level and affixal negation at the sub-word level. The data show that the distribution of negation is significantly different in the two document types, with explicit negation more frequent in the clinical documents than in the scientific publications and affixal negation more frequent in the journal articles at the type level and token levels. All code is available on GitHub\(^1\).

Natural Language Processing; Data Mining; Linguistics

Introduction

Natural language processing (the treatment of human language by computers) is increasingly used in health care and in biomedical research [1–4]. Negation is a frequent cause of errors in language processing [5–9]. This has stimulated a considerable amount of work on negation in clinical documents (e.g. the classic work cited above and recent work summarized in [10]), and a lesser amount of work on negation in scientific literature (e.g. the work summarized in [11–14], as well as scientific literature corpus creation efforts [15–19]). However, while that work has made considerable progress, it has focused almost exclusively on explicit negation by words with phrasal scope, such as no and not. In contrast, negation at a sub-word level—what has been called affixal or morphological negation, such as the de- in dephosphorylate or the a- in afebrile, meaning without fever—has received very little attention in biomedical language processing. This is a gap in the literature, as this kind of negation has implications for many things in biomedical language processing and biomedical communication in general, ranging from lexicon/terminology design, to readability of and access to health care information by non-specialists, to the performance of natural language processing applications. Furthermore, the majority of work on negation in the biomedical domain has focused on evaluation of system performance; very little of it has looked at distributional characteristics of negation in the relevant genres. This is a serious gap because it has implications for our understanding of the system performance that is the topic of most work on negation in the domain. This paper addresses both of those issues. In particular, we look at both clinical data and scientific literature and compare them with respect to their distributions of two kinds of negation: explicit negation (words such as no and not), and morphological negation (the a- in afebrile). Along the way we discuss a data set that we have prepared containing several thousand ambiguous words marked as to whether or not they begin with a negative prefix. The null hypotheses that we evaluate are that there are no differences in the distribution of negation between clinical and scientific biomedical texts at any of the levels to be examined; as will be shown, in fact there are such differences at the syntactic level and at the morphological level, and the differences are sometimes large.

This paper takes a distributional and descriptive approach because in text mining and natural language processing, knowledge of the distribution of any linguistic phenomenon can help us predict the contribution of that phenomenon to error rates in our applications. Distribution of negation in particular is important both in natural language processing and in language science more generally. In a paper that we discuss in more detail below, [20] Wu et al. point out that distributional characteristics of linguistic phenomena can have deep implications for evaluating not just individual systems, but also for evaluating the literature on a topic overall, where the performance that is reported in a paper may accurately describe the performance of a system when it is optimized for a specific dataset, but not be generalizable. This can lead to the conclusion that a particular problem is essentially solved, when in fact all that has been solved is dealing with a particular definition of that problem in a specific data set. In particular, Wu et al. point out that there has been considerable work on negation in biomedical text, particularly in clinical text, with a smaller body of work existing on negation in scientific journal articles. They describe a number of published solutions to negation in clinical texts, as well as observe that they are optimized to particular genres of text, and that those solutions do not necessarily generalize well at all.

From the point of view of system development and evaluation, knowledge of the distribution of a linguistic phenomenon can help select suitable document sets to use for some specific task type (at the granularity of, say, parsing, coreference resolution, etc.). It can help prioritize module development, and in the case of negation, it may interact with usability of tools based on natural language processing, given what we know about human processing of negation from psycholinguistic studies: negated assertions are more difficult to process [21]. Distributional information can be used as a form of prior

\(^1\)https://github.com/KevinBretonnelCohen/NegationDistribution
knowledge in machine learning applications that allow supervised under- and over-sampling [22].

Finally, to the authors’ knowledge, there is very little literature that explores translational issues in negation. All work that we are aware of in the biomedical domain has looked either at clinical texts, or at published biomedical literature. To address that gap in the literature, we have compared two very different genres with relevance to translational research: on the one hand, scientific journal articles, and on the other hand, clinical documents.

Context of the present work

There has been a small amount of previous work on the distribution of negation. Yaeger-Dror and Tottie [23] focused on spoken versus written English and found differences in the distribution of affixal and explicit negation when comparing spoken versus written language. Chapman et al. [6] examined the distribution of explicit negation within a genre and found that it may be Zipfian, noting that “The negation algorithm was triggered by sixty negation phrases with just seven of the phrases accounting for 90% of the negations.” Subsequent work found this to be true across multiple Germanic languages, as well as the Romance language French [24]. Cohen et al. [25] compared the abstracts and bodies of full-text journal articles and found that article bodies had a higher percentage of explicit negatives, at 5.3/thousand words versus 3.8/thousand words in abstracts (p < .01 by Mann-Whitney-Wilcoxon), concluding that this was relevant to the relative difficulty of information extraction from the two text types. Verspoor et al. [26] made the same measurements in Open Access versus traditional journals, finding no significant difference between them and using that to argue that Open Access journals are representative of the biomedical literature as a whole. Kjellmer studied some of the interesting problems of affixal negation of adjectives in English, such as which adjectives can and cannot be negated (e.g., English has unkind, but not uncruel), and includes data on distribution of affixal negatives across types of adjectives [27]. Globally, this body of work work can be summarized as showing that the distribution of negation is structured, and that it can be shown to vary in interesting ways (or not) both within and across genres. However, it remains the case that the literature on differences between morphological and explicit negation is very small, to the point that there have not been opportunities to evaluate the replicability of the associated findings, and the topic has not been addressed at all in the biomedical domain.

Wu et al. [20] point out that one of the consequences of the sublanguage nature of clinical documents is that there is a limited number of ways to express negation; this is true, but previous studies of negation in clinical literature have focused on negation at the syntactic level. Here we extend the domain of inquiry into a previously unstudied part of the grammar of biomedical text: the morphological level. Wu et al. pointed to the morphological differences in annotations as a possible explanatory factor that was uncharacterized. The work discussed here adds a considerable amount of data to that discussion, adding the ability to compare clinical data (the subject of the small amount of previous observations about distribution of negation in the biomedical domain) with data on scientific publications. Using the same processing on both data sources makes the results directly comparable, which has not been the case with previous work.

Methods

Materials

Since the goals of this study are translational in nature, the materials for this work were drawn from the clinical domain and from the biomedical literature: MIMIC II progress notes on the one hand [28,29] and the CRAFT corpus on the other [30–32]. The rationale behind this choice of domains is that they are close to the opposite ends of the spectrum between bench (the mouse being a common model organism) and the bedside. Other choices could potentially be useful, e.g. journal articles with a clinical orientation, other kinds of clinical documents, etc.

MIMIC II progress notes: Half a million words of physician-written progress notes from the MIMIC II corpus. They reflect the status of patients in the Intensive Care Unit.

CRAFT corpus: A corpus of scientific journal articles in the domain of mouse genomics, previously shown to be representative of the biomedical scientific literature [26].

Explicit negation

We took samples of 10,000 consecutive words from both document types, for a total of 440,000 words each (the closest total sample size to the number of words in CRAFT, the smaller corpus). We counted the number of explicit negative words per 10,000-word sample. The set of explicit negatives that we counted was: no/not/none/denies/nothing. Details of the normalization can be found in the script, available on GitHub and named negativesEvery10KWords.pl. (One could argue about the completeness of the set of explicit negatives that was used in the experiment, but any omissions would affect both text types proportionally and would not be likely to change the overall conclusions of the study.)

Affixal negation

All word types in both corpora were collected, and after normalizing for case and punctuation, the number of tokens of each type was counted. To clarify the meanings of the terms type and token: the word denaturation occurs 9 times in the CRAFT corpus. The word ativan appears 22 times in our sample of the MIMIC II corpus. These represent two types (denaturation and ativan), and a total of 31 tokens. (See script directoryToTypeTokenCounts.pl on GitHub for details of the normalization.) Then we extracted all words beginning with any string that can be a negative prefix in English. To ensure objectivity, we obtained definitions of the set of negative prefixes in English from neutral third parties, named in a file on GitHub. This step produced a list of 5,196 words that can be thought of as ambiguous with respect to whether or not they begin with a negative morpheme. The extracted words were examined manually and classified as actually containing a negative prefix, or not. All words from both document sets were presented as single words in isolation.

With the judgements about which words did and did not begin with a negative prefix, along with the counts of each of those words, we calculated the total number of tokens beginning with an actual negative prefix in each document collection.

To build the set of words beginning with ambiguous strings, we first searched the two text collections for words beginning with the following character sequences, all of which are listed as negative prefixes in the 3rd-party sources listed on the GitHub site: un, no, a, de, dis, anti, il, im, in, and ir.

GitHub site: [GitHub link]

Details of the normalization can be found in the script, available on GitHub and named negativesEvery10KWords.pl. (One could argue about the completeness of the set of explicit negatives that was used in the experiment, but any omissions would affect both text types proportionally and would not be likely to change the overall conclusions of the study.)

The extracted words were examined manually and classified as actually containing a negative prefix, or not. All words from both document sets were presented as single words in isolation.
The resulting set of words can be thought of as ambiguous with respect to whether or not they begin with a negative morpheme, since it contains words such as *antipapiotic* (CRAFT, 6 tokens), *immature* (MIMIC, 177 tokens), and *desaturation* (MIMIC, 72 tokens), which begin with negative morphemes, and *anticipated* (CRAFT, 3 tokens), *improved* (MIMIC, 205 tokens), and *detailed* (MIMIC, 809 tokens), which do not. These are the words which were manually classified as beginning with a negative morpheme, or not.

**Guidelines**

We developed the guidelines in three rounds, consisting of

1. a test of an initial set of guidelines on Amazon Mechanical Turk,
2. a subsequent test of a revision of the guidelines on Amazon Mechanical Turk,
3. …and then review of the guidelines by all authors.

In developing the Mechanical Turk tasks, we took note of the ethical guidelines for crowdsourced linguistic data in [33].

Even after those three rounds of guideline development our domain-expert annotators—one of whom had written the guidelines—still had questions about some specific cases. The final set of guidelines is available on GitHub.

To ensure the clarity and consistency of the guidelines and the neutrality of the resulting counts, the data was double-annotated. The annotators represent typical readers of the materials in question: an emergency room physician and a former registered cardiovascular technologist with a PhD in linguistics and a specialty in biomedical language.

For the final annotation step, the word types from CRAFT and MIMIC II were combined into a single file and randomized (both with respect to corpus and with respect to ranking within each corpus). The inter-annotator agreement was 0.94 before resolution, and the entire calculation of agreement is documented on GitHub.

Finally, we used a two-tailed t-test to assess the statistical significance of the observed differences in explicit negation, and the chi square test for the data on affixal negation.

**Replicability, repeatability, and reproducibility**

All scripts, annotation guidelines for the affix study, and judgments of the individual annotators are on GitHub (see URL at the bottom of the first page). The annotation project and analysis were repeated by an independent third party to ensure that it was replicable. CRAFT is available at bionlp.sourceforge.net. MIMIC II requires a data use agreement, but is freely available.

**Results**

**Explicit negation**

The distribution of explicit negatives for the two document collections is shown in Figure 1. The distributions are quite different, with a mean of 111 per 10,000-word sample for the MIMIC II progress notes, and a mean of 31 per 10,000-word sample for the CRAFT corpus. A Welch 2-sample t-test shows a statistically significant difference, \( t = -27.092 \), \( df = 53.822 \), p-value < 2.2e-16.

**Affixal negation**

The distribution of morphologically negated and non-negated words is shown in Table 1, along with their ratios on the type level and on the token level. The distribution of morphological negation is different at the type level in the two genres, chi square = 8866.8, \( df = 1 \), p-value < 2.2e-16, with the journal articles having a higher incidence of morphologically negated types (0.028) than the clinical documents (0.017). Additionally, the distribution of morphological negation is also different at the token level in the two genres, chi square = 14338, \( df = 2 \), p-value < 2.2e-16, with the journal articles having a higher incidence of morphologically negated tokens, although the magnitude of the difference is smaller than that at the level of types (0.013 for CRAFT, 0.012 for MIMIC II).

**Table 1 - Counts and ratios of negated types and tokens.**

**Discussion**

The results of the hypothesis tests can be summarized thus: the distributions of explicit negation are different between the two genres by two-tailed t-test, with the clinical notes having a much higher incidence of negation than the journal articles. The distribution of affixal negation is different at the type level in the two genres by chi square, with the journal articles having a higher incidence of morphologically negated types. The distribution of affixal negation is also different at the
In a 2014 paper with far-reaching implications for the study of negation, and indeed for machine learning in natural language processing in general, Wu et al. [20] concluded from their analysis of generalization versus optimization in clinical-domain negation detection systems that the best way to improve performance in negation detection is to manually annotate more data. In particular, they refer not to increasing the sizes of the corpora that we already have, but to annotating negation in data drawn from other distributions besides the corpora that are already available. The work reported here is a contribution in that direction, as one of the results of the work is a large set of words from clinical records and scientific journal articles, available at the GitHub repository, that have been annotated for the presence of a derivational, prefixal negation morpheme. Because the methodology that we describe here can yield relatively good judgements with good inter-annotator agreement, this two-corpus study can be rapidly extended to additional scientific and clinical genres.

In addition to the relevance of these findings to biomedical language processing, there are also implications for the construction of semantic resources for the domain. The community’s investment in lexical, terminological, and ontological resources continues to be strong. The findings that we report here have implications for the approach to building those resources. Modern lexical-semantic resources such as PropBank and VerbNet [34–36] include separate entries for predicates that are related by the negative prefixes that have been studied in this paper. The Open Biomedical Ontologies seem to be following this strategy. However, since they have large numbers of “reversible” state-changing predicates, they do not seem to be keeping up, and if they can, may find the explosion in the number of terms to be overwhelming. For example, the Gene Ontology currently (file go-basic, version releases/2016-12-24) contains 8 terms that begin with phosphorylation (up from 6 in 2014), but only has 3 of the corresponding terms beginning with dephosphorylation (unchanged from 2014). A mechanism for dealing procedurally with this kind of prefixation could considerably reduce the maintenance load of biomedical resources like the Open Biomedical Ontologies. (Van Son et al. [37] gives an idea of what an affixal negation resource might look like, demonstrating the feasibility of the necessary annotation tasks.) Thus, there are many potential applications for the distributions that are reported on here.

Reproducibility

The code and data necessary to repeat/replicate this analysis are available for download at the GitHub repository named at the bottom of the first page of the paper. Future work that would be potentially revealing in terms of the reproducibility of the results reported here include at least the following, some of which are variations on the approach and some of which sample different populations:

- Using different sources of negation patterns, such as the most recent set of NegEx patterns, or those that could be mined from negation-annotated corpora, such as BioScope [12] and the BioNLP-ST shared task corpora [11,14].
- Expanding from the MIMIC II physicians’ notes to other types of clinical data, from the CRAFT corpus to other scientific domains, and from English to other languages.

Acknowledgements

The work reported here was supported by NIH grants LM008111 and LM009254 to Lawrence E. Hunter, and NSF grant IIS-1207592 to Lawrence E. Hunter and Barbara Grimpe. Cohen’s work was supported by Hunter’s grants, by grant AHRQ R21HS024541-01 to Foster Goss (as was Goss’s), and by generous funding from Labex DigiCosme (project ANR11LABEX0045 DIGICOSME), operated by ANR as part of the program Investissement d’Avenir Idex Paris-Saclay (ANR11 IDEX000302), as well as by a Jean d’Alembert fellowship from the Fondation Campus Paris-Saclay as part of the “Investissement d’Avenir” program operated by ANR. PZ received funding from the European Union’s Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant 676267.

The authors thank Tiffany Callahan, who repeated the analysis to ensure that it was replicable, finding a bug in the process. We assure the excellent MEDINFO reviewers that the next paper will be titled Of mice and men, as suggested. We also thank Stephen Wu, Wendy Chapman, and the members of the group Information Langue Ecrite et Signe des de l’Informatique pour la Mécanique et les Sciences de l’Ingénieur, Centre National de la Recherche Scientifique for discussion. Mayla Boguslav, Harrison Pielke-Lombardo, Jingbo Xia, and Elizabeth White gave helpful comments on the manuscript.

Extracting Sexual Trauma Mentions from Electronic Medical Notes Using Natural Language Processing

Guy Divita, Emily Brignone, Marjorie E. Carter, Ying Su, Rebecca K. Blais, Matthew H. Samore, Jamison D. Fargo, Adi V. Gundlapalli

Abstract

Patient history of sexual trauma is of clinical relevance to healthcare providers as survivors face adverse health-related outcomes. This paper describes a method for identifying mentions of sexual trauma within the free text of electronic medical notes. A natural language processing pipeline for information extraction was developed and scaled to handle a large corpus of electronic medical notes used for this study from US Veterans Health Administration medical facilities. The tool was used to identify sexual trauma mentions and create snippets around every asserted mention based on a domain-specific lexicon developed for this purpose. All snippets were evaluated by trained human reviewers. An overall positive predictive value (PPV) of 0.90 for identifying sexual trauma mentions from the free text and a PPV of 0.71 at the patient level are reported. The metrics are superior for records from female patients.

Keywords: Natural Language Processing; Information Retrieval; Trauma and Stressor Related Disorders

Introduction

Patient history of sexual trauma is of great clinical relevance to healthcare providers. Sexual trauma is associated with a wide range of adverse health-related outcomes. These include psychiatric comorbidities such as PTSD, depressive disorders, anxiety disorders, and alcohol and drug related disorders [1-4], as well as medical comorbidities such as chronic pulmonary disease, liver disease, and hypertension [1-5]. Adverse social determinants of health include sexual re-victimization, homelessness, and suicide [6-9]. The initial psychiatric sequelae of sexual trauma, in the absence of intervention, may accumulate to affect a broad range of health and psychosocial domains, with symptoms often persisting for several years following the incident. Despite these clear implications for health status and health care needs, sexual trauma is generally poorly documented in healthcare settings [10].

The documentation of sexual trauma in administrative data such as International Classification of Diseases (ICD) coding is poor and likely under-represents the true prevalence of this complex problem. Furthermore, documentation of a history of sexual trauma in the free text of medical notes is also limited. While this may be a preference of the patient or practice of providers, the end result may be decreased access to appropriate trauma-informed care for survivors of sexual trauma [11].

The free text of the electronic medical note presents an opportunity to extract additional details pertaining to exposure to sexual trauma. Patients have the opportunity to disclose or express details of an experience of sexual trauma of any kind to a provider during a healthcare encounter. In addition, long term clinical follow-up allows the patient time to become comfortable with the provider and clinic, which may further facilitate disclosure.

This paper describes a method for identifying positively asserted mentions of sexual trauma within the free text of VHA electronic medical notes. Sexual trauma mentions are identified by a dictionary lookup algorithm using a curated dictionary of terms related to sexual trauma. The method also identifies the assertion status of the trauma mentions. The performance metrics, challenges, and relevant note types identified in this study will inform future NLP applications. Our novel application of NLP has broad generalizability in that it can be extended to other healthcare settings, as references to sexual trauma are likely universal.

As opposed to private and public health care systems in the US, Veteran’s Health Administration (VHA) represents an integrated health care setting in which history of sexual trauma is regularly identified and documented. In 2004, VHA initiated universal screening of all Veterans seeking care in its medical facilities for exposure to sexual trauma during military service (military sexual trauma, MST). Currently, over 90% of new VHA users are screened, and 22% of women and 1% of men screened report exposure to sexual trauma during military service (military sexual trauma, MST). Currently, over 90% of new VHA users are screened, and 22% of women and 1% of men screened report having experienced this type of sexual trauma [12]. Under this model, many thousands of patients with a history of sexual trauma have been identified, facilitating access to specialized care designed to mitigate adverse outcomes. However, sexual trauma is underreported, and several estimates suggest that the prevalence of MST is much higher than official estimates based on structured screening [13, 14]. Additionally, screening focuses solely on sexual trauma occurring in a military setting, leaving survivors of childhood sexual trauma or non-military sexual trauma at risk of unmet health needs.

With respect to the VHA electronic medical record, a history of MST may be documented in several ways. Structured data include the result of a screen for MST described above. In the free text of electronic medical notes, there are a variety of techniques used by providers to document the results of screening questionnaires for MST. These include MST status indications written using grammatically well-formed sentences, but more frequently they appear in boiler-plated check box, question-answer, or slot value format. In this, special attention had to be given to identifying MST status boiler-plated mentions. It was necessary to further examine such boiler-plated mentions to insure that those
mentions were a true MST status indication. A number of boiler-plate mentions, which are in question-answer form are missing the answer. This includes missing indications in check box and slot-value formats as well. There is a further confounding of the boiler-plated format wherein the check boxes and slot-values are null; in this situation, it is not clear whether the provider has administered the MST survey with a checklist of items to discuss or whether the answer is null.

V3NLP Framework

The work described in this paper is built using the V3NLP Framework [15]. This framework provides a set of functionalities designed for building NLP applications that combine one reader and one or more writers around a pipeline of annotator components. While the V3NLP Framework is built upon the APACHE UIMA [16] platform, it utilizes UIMA-FIT [17] and Leo [18] functionalities that simplify and work around the complexities inherent in UIMA.

Related Work

The task of identifying mentions of sexual trauma in electronic medical notes using NLP is related to work developing social phenotyping using VHA electronic medical records described by Gundlapalli et al. [19]. The dictionary used for the sexual trauma task has been curated by subject matter experts and VHA clinical providers, and constrained to only include mentions of direct evidence of sexual trauma.

Methods

The Patient Cohort

This work was conducted using the extraction of a cohort of 10,000 male and 10,000 female patients randomly chosen from veterans who served during recent wars in Afghanistan and Iraq who had also received medical services in VHA medical facilities for the first time during FY2010-FY2014. All outpatient electronic medical notes in the 12 months following the date of the MST screen were extracted.

The clinical notes were extracted from VHA’s Corporate Data Warehouse using the Veterans Informatics and Computing Infrastructure (VINCI) [20].

Natural Language Processing Pipeline

This sexual trauma extraction task is accomplished by a dictionary lookup mechanism within a larger NLP pipeline. A UIMA pipeline [16] was assembled using components of the open source V3NLP framework [15]. UIMA pipelines are composed of a series of annotators, where the output of one annotator is in turn the input to the next. The annotators chosen at the front of the sexual trauma pipeline decompose the text into constituent document element parts [21] including sections [22], content headings, lists, sentences, lines, tokens, slots and their values, questions and their answers, and check boxes, as well as other boiler-plate entities. The dictionary lookup annotator provides single and multi-word term annotations (more about the dictionaries employed in a subsequent section). An annotator created for the sexual trauma task was employed to transform term annotations with sexual trauma categories into sexual trauma annotations. An annotator using rules from conTEXT [23] provided assertion attributes (negation, assertion, subject, hypothetical, conditional, historical) to sexual trauma annotation, followed by a filtering annotator to remove intermediate, but no longer needed, annotations. Figure 1 shows the annotators that make up this pipeline.

Term Identification Annotator

The term identification annotator creates term annotations from longest matching spans within sentence boundaries. This is the dictionary lookup portion of the pipeline. Term lookup uses the same lookup algorithm described in Divita et al [24]. Dictionary terms include one or more categorizations or semantic types. For this task, multiple dictionaries are used, a distinctive V3NLP Framework functionality. General and medical terminology is covered through the use of the SPECIALIST Lexicon [25]. The identification of general and medical terminology is used to absorb multi-word terms such as “MST Survey” that would otherwise cause ambiguity and fallacious matches if seen as individual words.

A dictionary of psychosocial risk factors created by domain experts in the field of homelessness formed the initial lexicon. Sexual trauma and related terms were extracted and further curated by subject matter experts with an understanding of sexual victimization. Additional terminology was found from traversing real-world usage from n-grams from a representative corpus [26]. In all, the domain dictionary includes 96 terms.

Thirty-five negative evidence terms were employed to reduce false positives. These included items like book and pamphlet. Such mentions often indicated that the contents of a book or pamphlet was the subject of a discussion during individual or group therapy sessions for sexual trauma survivors rather than a reference related directly related to sexual trauma.

Addressing Boilerplated Content

VHA electronic medical notes are replete with boiler-plated text [27, 28], similar to other electronic medical record systems. Such text is telegraphic, underspecified shorthand used to convey meaning by shortening the lengthy narrative that would otherwise be required. There is a large amount of variety and variability to the boiler-plated content within clinical text as providers are given the freedom to develop their own templates to facilitate documentation. Such content includes check boxes, slots and their values, questions and their answers, and pre-written prose text that has been copied-and-pasted into the record. The assertion semantics of sexual trauma mentions found within check boxes, slots and their values, and questions is different for each of these entities. For instance, a MST mention contained within the content heading of a check box is only asserted if the box is checked. A MST mention found within the content heading of a slot and filler structure is only asserted if the value or filler is filled out and has a non-negative kind of value. The assertion semantics are similar for sexual trauma mentions within questions. Integrations of prior work in this area was extended to this pipeline [21].

Exposure to boiler-plates involving sexual trauma mentions pointed to a challenging issue of boiler-plate forms involving assertions that a topic was discussed, rather than a positive assertion that the patient had the condition. An early review from a small seeded set of notes identified a number of boiler-plate MST
surveys. Mentions from these surveys were false positives more often than not. The domain lexicon was subsequently augmented with eight identifying patterns from these boilerplates, and labeled with an ignore category to filter mentions coming from these boilerplates out.

**Sexual Trauma Annotator**

The sexual trauma annotator, the only annotator custom-developed for this project, looks for sexual trauma terms as anchors within the bounds of each sentence or slot value structure. Once found, negative evidence was looked for within this same window. Anchors found without any negative evidence were made into sexual trauma annotations.

**Scaling Up the Pipeline**

The availability of a large set of records presented the opportunity to scale up the pipeline to efficiently handle hundreds of thousands of records in a reasonable amount of time. An application using the V3NLP Framework thread-based scale-up functionality [29] was used to wrap around and replicate the pipeline. This functionality allowed the process to start up with an initial number of pipelines, and, over time, add additional pipeline instances if there are enough resources available on the machine.

This task provided a use case to build out and include a mechanism to sample output for quality and efficacy purposes while the process is running. The sampling mechanism involves creating snippets around mentions at a specified sample rate. Visually, a snippet involves the line in the text a mention is found, plus lines above and lines below. Each snippet includes enough metadata to trace back to the location in the original document; it also aggregates information about the categorization of the mention, allowing analysis using just the snippets. Snippets are aggregated and put into VTT [30] formatted files to allow for quick human review and validation (Figure 2).

**Evaluation**

Sexual trauma mentions have been noted to be a rare event in clinical records, precluding a de-novo human review of random records to find mentions, and also precluding an evaluation that identifies the mentions this algorithm would miss. Rather, the snippets around each asserted mention were created from this cohort to evaluate those that the NLP extracted. All asserted snippets were reviewed and classified by three reviewers. Each reviewed snippet was classified as either a true positive or false positive. This review gives a positive predictive value (PPV) for the method. PPVs were also calculated for the snippets. The snippet decisions were aggregated to the patient level to give patient level PPV metrics. Gender was carried along, allowing PPV metrics to be detailed by gender.

The reviewers indicated for each mention whether the mention indicated childhood sexual trauma, adult (non-military) sexual trauma, or military sexual trauma. These curated annotations now form a reference corpus to guide work to more specifically identify kinds of sexual trauma. The reviewers went through three iterative rounds of training on sets of 200 snippets and guideline tuning until the inter-annotator agreement amongst them reached 0.80.

**Results**

Of the initial sample of 20,000 patients, 13,501 had electronic medical notes in the timeframe designated for this study. These patients had a total of 362,546 notes that were processed using the NLP pipeline. A total of 8,299 asserted mentions were extracted by the pipeline from 5,357 documents (1.5% of all documents) and 1,220 unique patients (9% of all patients who had electronic medical notes).

**Performance Metrics of V3NLP Pipeline for Sexual Trauma Mentions**

As shown in Table 1, the overall precision (or positive predictive value) for identifying positively asserted sexual trauma mentions as validated by a human review is 0.90. The performance was nearly double for identifying mentions from the free text of electronic medical notes of female patients as compared to male patients. When the mentions were aggregated to the patient level, the overall precision decreased to 0.71. The metric for female patients was superior as compared to male patients.

**Observations**

Mentions were found in 411 document types. Figure 3 shows the top 20 document types covering 50% of the mentions extracted by the V3NLP pipeline.
Performance Metrics
The scaled-out NLP pipeline processed 362,359 documents in 5.7 hours, processing at a rate of 57 ms per record. Ten concurrent pipelines were employed to achieve this performance.

Failure Analysis
Half the false positive snippets were reviewed and classified into eight categories (Table 2). Of note, failures having to do with negation account for 39% of the total failures. The majority of these were intertwined with boiler-plated (and in particular, check box and question formatted) text where the negation was too distant to be picked up, on subsequent lines or in a multi-column format (not currently handled), or using patterns not in our negation pattern expressions, such as neg. An additional 24% of the false positives came from statements that were overly broad in meaning: where two relevant and non-relevant mentions of the false positives came from statements that were overly broad in meaning: where two relevant and non-relevant mentions were used together with no ability to determine which one should be asserted (example of second type of false positive in Table 2).

A prominent error was observed within the set of false positives: MST as an abbreviation for Mountain Standard Time in the US, an oversight to be accounted for going forward.

Discussion
A history of sexual trauma is not well documented in the electronic medical records of patients. However, it is important to identify sexual trauma survivors so that they may be offered appropriate trauma-informed services to mitigate adverse health-related outcomes.

This study demonstrates the feasibility of identifying and extracting positively asserted mentions of sexual trauma from the free text of electronic medical notes. The overall PPV of the NLP pipeline is high at the patient level (0.71) and even higher at the mention level (0.90), particularly when identifying sexual trauma in female patients.

With regard to which type of notes and providers are documenting sexual trauma in the free text of electronic medical notes in VHA, as expected, notes from mental health, psychiatry, and psychology providers were among those with the highest hit rate. A particular type of note which is specific to VHA is a prominent error was observed within the set of false positives: MST as an abbreviation for Mountain Standard Time in the US, an oversight to be accounted for going forward.

Follow-on Work
The negative snippets need to be reviewed to see what false negatives are being inadvertently missed by the NLP pipeline. These snippets have been generated and human review is planned. When completed, this body of work will provide the true negatives and false negatives counts needed to compute precision/recall metrics.

Classifications of the sexual trauma annotations into adult, childhood, or military sexual trauma types will be added based on evidence statements found within the bounds of the snippet window. A preliminary analysis of such evidence in the manually classified snippets suggests that a high proportion of annotations may be successfully classified. Sexual trauma indicators from structured data including MST screening status will be correlated with these findings to provide a control vs positive cohort to calculate precision/recall f-metrics.

Conclusions
Sexual trauma mentions are rarely noted in electronic medical notes of VHA patients. In our study, only 9% of patients positively asserted sexual trauma mentions in the free text of electronic medical notes and these were extracted from 1.5% of the document corpus. This paper demonstrates a technique to identify positively asserted sexual trauma mentions (words, phrases, and statements) from the free text of electronic medical notes of VHA patients using natural language processing.

Documents with the highest hit rate of mentions as well as reasons for false positivity of the outputs are reported. The methods described here are generalizable and portable to documents from other health care systems outside VHA that use electronic medical record systems. This paper lays the foundation for techniques to further classify patients with sexual trauma with the intent to identify Veterans with military sexual trauma to better serve this vulnerable population.

Abstract

There is need for cataloging signs and symptoms, but not all are documented in structured data. The text from clinical records are an additional source of signs and symptoms. We describe a Natural Language Processing (NLP) technique to identify symptoms from text. Using a human-annotated reference corpus from VA electronic medical notes we trained and tested an NLP pipeline to identify and categorize symptoms. The technique includes a model created from an automatic machine learning model selection tool. Tested on a hold-out set, its precision at the mention level was 0.80, recall 0.74 and an overall f-score of 0.80. The tool was scaled-up to process a large corpus of 964,105 patient records.

Natural Language Processing; Machine Learning; Diagnosis

Introduction

There is need for more granular data, in particular, signs and symptoms, from the medical record in clinical and research domains such as quality improvement, population health metrics, patient recruitment for clinical trials, surveillance for adverse events, post-marketing surveillance, genomic medicine (genotype-phenotype associations), and epidemiologic studies. Structured data elements holding signs and symptoms have been shown to be underreported in clinical data repositories[1]. Advances in natural language processing (NLP) have begun to unlock information from the free text of medical notes[2]. This paper reports on an effort to extract signs and symptoms from clinical text using NLP. While prior work focused on specific signs and symptoms or worked within limited domains, this effort is more general.

Symptom Definition

Symptoms are the essence of the patient’s experience of illness. A medical encounter starts with what a patient conveys to his or her provider in the form of symptoms and concerns. The traditional distinction between symptoms and signs is that symptoms are subjective experiences whereas signs are objectively observed. A more formal definition of a symptom is that it is “a bodily feature of a patient that is observed by the patient and is hypothesized by the patient to be a realization of a disease [3]. An operational criterion of a symptom includes the elements of patient experience, abnormal characteristics, and clinical relevance.

Symptoms are captured in the medical record as reported by providers. The patient’s own words are filtered through the experience of the medical provider. Moreover, not all of the symptoms expressed by the patient are entered into the medical record [4]. Often, there is paraphrasing and summarization. When a symptom is difficult to paraphrase or capture in a single concept, it may be quoted verbatim in the record using quotation marks. Once the medical documentation is complete and the encounter is closed, there are only inferred references to the symptoms. Some, but not all symptoms are reflected in problem lists or ICD-9-CM coding of the medical encounter[5] or inferred on the basis of prescribed medications. Forbush noted that while problem lists included on average three symptoms per document, six symptoms on average are mentioned in the clinical note. Most documentation of symptoms is in the form of free text in clinical notes.

Common to other NLP extraction tasks, this work recognizes symptoms by a dictionary lookup methodology but with a large (over 92k) symptom concept dictionary. Additional notable methods described in this paper include recognizing common lexical patterns indicative of symptom phrases, recognizing only asserted mentions and an optimized machine learned component to filter out fallacious symptom phrases.

The impetus for this work revolves around improving patient care for veterans. US military personnel who have served in combat theaters experience various symptoms and illnesses attributable to their deployment [6, 7]. Of the most common conditions noted in administrative data of recently returned combat veterans are “non-specific signs and symptoms” represented by ICD-9-CM codes 780-799 [7]. While this is an appropriate starting point for epidemiologic studies, there is a need to identify symptoms in free text to address the true extent of post-deployment illnesses among Veterans seen in US Department of Veterans Affairs (VA) medical facilities.

More broadly, tracking and assessing the presence of symptoms is useful for surveillance of syndromes[8], staging of disease, and evaluation of treatment response. Phenotyping, which involves the characterization of a set of clinical features, is incomplete without the inclusion of the patient’s subjective experience.

The objective of this project was to develop a natural language processing (NLP) pipeline that reliably identifies and extracts mentions of any positively asserted symptoms from the free text of clinical notes. We also address challenges facing current information extraction techniques such as the vast heterogeneity of expression and boilerplating commonly seen in electronic medical records.
Related Work

Extracting concepts from the free text of medical records (clinical text) has been the holy grail of NLP researchers. The challenges of processing clinical text over biomedical text have resulted in slow progress over the years[9]. Starting with outpatient and emergency department encounters, efforts have been underway to process the free text associated with chief complaint data, problem lists for continuity between visits, family history, chest x-ray reports, pathology reports and discharge summaries[10]. Several studies have focused on the free text of the medical encounter (both outpatient and inpatient) in looking for clues to adverse events or for bio surveillance[11]. Limited studies have focused on signs and symptoms associated with specific diseases or conditions; these include infectious diseases such as pneumonia[12] and influenza[13], and cancer staging[14]. Major impetuses to advance NLP of clinical text have been the serial i2b2 challenges. The 2010 challenge focused on problems, assertions and relationships[13]. Diligach, et al.[16] mentioned symptom extraction as a component of discovering body site and severity within clinical texts via cTAKES, but the signs and symptoms were not the focus of this work. More recently, Robert[17] describes identifying symptom mentions through semantic categorization, extracting patterns that involve spatial relations between disorders and anatomical structures from well-formed prose. However, a very limited number of studies that have focused on symptoms expressed by patients in the body of the electronic note; there are virtually no studies on looking broadly at symptoms across sets of patients.

Methods

Reference Document Corpus

A sample of 948 records were extracted from a cohort of 6 million patient records from Veterans that had recently returned from deployment in Afghanistan and Iraq. The clinical notes were pulled from the VA’s Corporate Data Warehouse (CDW) using the Veterans Informatics and Computing Infrastructure (VINCI) [18]. The records extracted were from 164 pre-selected document types. These records were human annotated to identify 5,819 positively asserted symptoms. Forbush describes the corpus characteristics and the annotation task.[5]. This corpus was divided into a training set and a hold-out testing set.

Natural Language Processing Pipeline

V3NLP Framework described in Divita et al[19] was used to build an NLP pipeline. V3NLP Framework is a framework built upon the Apache UIMA project[20].

This symptom extraction task is accomplished by a symptom dictionary lookup mechanism augmented with a statistical machine-learning filter. A UIMA pipeline was assembled using V3NLP framework components. UIMA pipelines are composed of a series of annotators, where the output of one annotator is in turn the input to the next. The annotators chosen at the front of the symptom pipeline decompose the text into constituent document element parts[21] including sections, content headings, lists, sentences, phrases, lines, tokens, slots and their values, questions and their answers, and check boxes, as well as other boilerplate entities. Additional annotators are included to add relevant features that will enable the downstream machine learning annotators to make an informed decision about whether a potential symptom is a true symptom or not. These annotators include a part of speech tagger and multi-word term identification to identify symptoms and non-symptoms. An annotator was created specifically for this task to identify potential symptoms by rules and patterns formed from annotations created by the dictionary lookup and document decomposition. The ConText assertion (negation, assertion, subject, hypothetical, conditional, historical) annotator [22] was included to add assertion attributes to potential symptoms to filter out negated and hypothetical symptom mentions such as denies pain, and pinprick.

A tail-end annotator was created for this task that employs a machine-learned model trained on 65 features gleaned from the upstream annotators. Figure 1 shows the production pipeline. The subsections that follow here describe the novel annotators within the symptom pipeline.

![V3 NLP Symptom Pipeline Used for Information Extraction from Free Text of VA Electronic Medical Notes](image)

**Figure 1 - V3 NLP Symptom Pipeline Used for Information Extraction from Free Text of VA Electronic Medical Notes**

**Document Element Decomposition Annotators**

**Section Identification**

Section identification is accomplished by a wrapper around OBSecAn[23], which is a sectionizer built from the attributes of what makes up sections from a database of 35,000 document templates used within the VA’s Veterans Health Information Systems and Technology Architecture (VistA) system.

**Term Identification Annotator**

The term identification annotator creates term annotations from longest matching spans within sentence boundaries. This is the dictionary lookup portion of the pipeline. Term lookup uses the lookup algorithm described in Sophia, an Expedient Concept Extraction Tool[21]. Tokens are looked up from right to left across a sliding window, matching longest matching chains of tokens from an index that is similarly composed of reverse order tokens from terms.

Terms within the dictionaries include one or more categorizations or semantic types. For this task, multiple dictionaries are used, a distinctive v3NLP functionality. General and medical terminology is covered through the use of the SPECIALIST Lexicon. The identification of general and medical terminology is used to absorb multi-word terms such as “pain scale”, that would otherwise cause ambiguity and fallacious symptoms if seen as individual words. A dictionary of 92,000 concepts (122,941 symptom forms) was created from Unified Medical Language System (UMLS) sources for this task, described by Tran[24]. Terms within this resource are tagged with a symptom category along with a set of 15 organ system sub-categories. A dictionary of idiosyncratic symptom phrases and symptoms not covered by the symptom dictionary (but seen in training data) is also employed. Terms from this resource are tagged with just the symptom category. A dictionary of symptom exceptions, or pertinent negatives, is included as a convenient way...
to quickly incorporate exceptions for specific purposes. Such was needed to address failures seen from the training set.

**Potential Symptom Annotator**

The potential symptom annotator is a rule-based method that identifies those terms in the text marked with a symptom category and creates a potential symptom if these instances are not observed to be in content headings. The method looks for symptom mentions identified in the dictionary lookup within a window of a sentence and no evidence that would indicate the mention is not a symptom before promoting the symptom mention to a potential symptom. There are nearly 123 thousand strings that could make up possible symptom mentions. Thus far, this technique wildly over-generates potential symptoms.

**Addressing Boilerplated Content**

Clinical records are replete with boilerplated text. Such text is telegraphic, underspecified shorthand used to convey meaning by shortening the lengthy narrative that would otherwise be required. There is a large amount of variety and variability to the boilerplated content within clinical text. Such content includes check boxes, slots and their values, questions and their answers, and pre-written prose text that has been copied-and-pasted into the record. The assertion semantics of symptom mentions found within check-boxes, slots and their values and questions is different for each of these entities. For instance, a symptom contained within the content heading of a check-box is only asserted if the box is checked. A symptom mention found within the content heading of a slot and filler structure is only asserted if the value or filler is filled out and has a non-negative kind of value. The assertion semantics are similar for symptom mentions within questions. Integrations of prior work in this area was extended to this pipeline[21].

**Additional Annotators**

Previous work in this area has described colorful and often vague descriptions of symptoms [5]. Such descriptions include mentions of an anatomical location. An additional symptom pattern includes a normal activity and modifiers to that normal activity with some negative or pathologic connotation. Symptom patterns also often included some indication of severity and duration. A similar insight was further observed in reviewing false positives: a large portion of them involved an activity with some kind of positive modifier. For instance, mentions of sleep prefixed by improved were seen as false positives, but not poor sleep. Those observations led to the compilation of a dictionary of modifiers, activities, and anatomical locations from UMLS resources and the creation of annotators for each.

We used multiple methods to build these resources. To form a high-level list of anatomical locations, we extracted UMLS concept unique identifiers (CUIs) from the Consumer Health Vocabulary (CHV) project files[25] and mapped them to the corresponding terms in the 2014 SNOMED CT terminology. These terms were hand-curated to identify the surface type of terms one finds in a patient’s symptom description. These were augmented with additional terms from the CHV’s last terminology, found in the 2011AA UMLS Metathesaurus release. To locate normal activities that also intersect with findings and functions, we extracted terms from almost every English vocabulary in the 2014AA Metathesaurus UMLS release that had a personal behaviors semantic type (Activity, Behavior, Daily or Recreational Activity, Individual Behavior, or Social Behavior) and then terms for semantic types Finding and Organism Function. The final list consisted of words occurring in both of these groups. For the modifiers list, we extracted every adverbial term from the UMLS Specialist Lexicon LAGR file (2014AA release). These were augmented with terms extracted from Patients Like Me symptom descriptions[26] and other symptom descriptions on the Internet. Those activities, modifiers, and anatomical locations within the sentence that included a potential symptom were added as features to the machine learning.

**Machine Learning Annotator: Training**

Initially, the dictionary and rule based mechanisms produced approximately nine false symptom mentions for each true symptom mention. An additional mechanism using the surrounding context was needed to filter down the false positive mentions. An annotator was developed to create Weka ARFF data rows filled with the feature values needed to train Weka machine learning models.[27] This annotator was placed at the tail end of the training pipeline building an ARFF training row for each mention found, noting if the mention also overlapped a human marked symptom. The subsequent ARFF file involving 16,353 training rows (5,819 positive examples, 10,534 negative examples) was used to create a machine learned model based on features and whether a human annotation overlapped the mention.

We used the automatic machine learning model selection tool built by Luo et al.[28, 29] to systematically test every classification algorithm in Weka and tune hyper-parameters. Compared to other similar ones, this tool can greatly reduce search time and classification error rate[29].

A technical note here: all mentions from all 948 notes were used to create the initial ARFF file. The rows from the ARFF file were then randomized, separated into a training set consuming 90% of the examples and a hold-out 10% used for testing.

**Machine Learning Features**

Features were chosen on the basis of adding evidence to identify a possible symptom as a true symptom. Five words to the left and to the right of the potential symptom and their respective parts of speech, and the part of speech of the potential symptom are included. In earlier versions, these were all grouped into a bag-of-words vector. The current iteration includes a feature for each of the fifth, fourth, third, second and first words to the left and right. Each feature includes enumerated values for what words appear in that position keeping words that appear more than 2 times in that position. Positional features intended to capture boilerplate clues are included, such as if the symptom appears in a checkbox, slot, value, question, list, or sentence, and if it is within a section. Also included are features associated with section information including the section name, if the line that the symptom appears in has been indented, and if the line includes camel case or all upper case. Activity, modifier, and anatomical part features are included based on the aforementioned insight. Also included is the assertion status of the symptom. An analysis of the attributes that contributed most to the outcome revealed that the symptom words, followed by symptom category, section name, the forth, and fifth words to the left and second and third words to the right were the most salient attributes.

**Production Pipeline**

A final annotator was developed that mirrored the machine learning annotator in that it creates Weka instances around potential symptoms, which are subsequently passed through the Weka trained model to classify whether they are true or not. Symptom annotation instances are created for those that are classified as true symptoms.

**Results**

The automatic machine learning model selection tool[28, 29] selected support vector machine coupled with stochastic
gradient descent as the classification algorithm. Tested on five iterations of different randomly assigned 90% training, 10% hold-out mentions, this model held a consistent performance for identifying asserted symptoms. Table 1 shows the information retrieval metrics for this model.

The model was folded into the NLP tool, scaled-up and run on a larger set of 964,105 records randomly chosen from the larger OEF/OIF cohort. The process ran 32 concurrent pipelines and took 11 hours to run, at an average speed of 40 ms per record.

In all, 59,412 symptom mentions were found from 19,914 documents from 10,397 patients. Figure 2 shows the distribution of organ system classes of the symptoms found in this cohort.

Failure Analysis

Snippets were generated around the false positives, and a sampling of 200 of these were categorized by type of failures. Issues in recognizing the numerous ways a mention can be negated are far more prevalent than any other type of error (57%). There were a number of false positives that could be plausibly true (16%). The rate of these are explainable due to the difficulty of the human annotation task. There were false positives caused by incorrectly parsing templates (5%) and checkboxes (5%). There was a smattering of other issues (21%) that could not easily be classified.

Discussion

Symptom extraction brings with it many challenges. Among them, a similarity and a continuum in context between signs, symptoms, findings, and diagnoses, making the distinction between these via explicit dictionary lookup and rules difficult. The term depression is a good example. It occurs 1160 times in this corpus. The depression mentions included references to patient reported symptoms, to provider observations and findings as well as the provider diagnoses. Our attempts at such without a machine learning component were disappointing. An additional requirement was the need to create a curated lexicon that significantly extended the pre-existing resources within UMLS. This additional resource was necessary to remedy the incompleteness of relevant terms within UMLS and to resolve the inconsistent distribution of symptoms across multiple UMLS semantic types. Moreover, our curated resource made it feasible to classify symptoms according to sub-type and organ system.

While the pipeline was developed specifically for VA medical notes, the general principles would be applicable to other large healthcare systems with commercial EMR’s that contain free text and semi-structured notes with templates. The technique is useful for applications extracting patient described indications, useful for adding to the phenotype for conditions. The lessons learned with regards to document element decomposition and identification of slot value pairs would also be portable and generalization to other settings where EMRs are used.

Limitations

We were not able to accurately calculate metrics at the document or patient level due to randomizing the mentions before splitting the training and testing sets.

Despite related work that has greatly expanded the ConText patterns and sped up the application of the algorithm, negation continues to be the greatest source of false positives, at a rate of 60%. Identifying a potential symptom is challenging for several reasons. The first is the observation that a large set of symptoms within the symptom dictionary are concepts that are a finding as well as a normal behavior, activity, or function. Such forms were observed to be a large portion of initial false positives. The heterogeneity of document types and the frequency and variety of boilerplated semi-structured elements continue to be troublesome. Despite the use of document element decomposition annotators, review of VA electronic medical notes reveals that symptom mentions are frequently found in telegraphic, boiler-plated lists, check boxes and questions.

The practice of using terms denoting symptoms with both an activity and a modifier also poses a challenge for information extraction. No easy mechanism was identified to mark the modifier polarity; such information would be of benefit for future iterations of the pipeline.

The slot value annotator along with the question and answer annotator need more refined techniques to catch idiosyncratic formats, easy to understand visually, but difficult to generalize into patterns and rules. Beyond this, it should be noted that the training set contains inconsistencies with how some boiler-plated sections were annotated or not annotated.

Word sense disambiguation, a challenge seen with the many acronyms and abbreviations, was not directly addressed in this pipeline. Co-reference resolution was partially addressed within the ConText algorithm which attributes if the symptom mention is attributed to the patient or other entity. Other than failures due to who to attribute the symptom to, co-reference resolution was not observed to be a point of failure. Neither issue rose to the levels of failure that negation or adequately parsing though check-boxes and questions currently pose.

The split for cross-validation was performed at the mention level. This may lead to some documents having mentions distributed into both the training set and the test set. Since a document may contain several occurrences of the same symptom, this is liable to result in an optimistic evaluation of the classifier results.

Future Work

This is being deployed in several applications where the focus is narrowed to specific conditions. We should learn how well the tool identifies specific kinds of symptoms from these studies. Recently added VINCI tools should allow us to compare our technique with cTAKES and CLAMP surrogates.
Conclusion

We have developed a technique to identify a variety of signs and symptoms within a wide range of document types. An exhaustive algorithm was used to find the most robust machine learning model to train with. The technique has been efficacy benchmarked with an f-metric of 0.80 against a hold-out set of 1 million records. The pipeline and application is distributed under an Apache License at http://nlpl.bmi.utah.edu/redmine/docs/v3nlp-framework

Abstract

Despite laws that require reporting of sexually transmitted diseases (STDs) to governmental health agencies, integrated surveillance of STDs remains challenging. Data and information about testing are fragmented from information on treatment and outcomes. To overcome this fragmentation, data from multiple electronic systems spanning clinical and public health environments were integrated to create an STD surveillance registry. Electronic health records, disease case records, and birth registry records were linked and then stored in a de-identified, secure server for use by healthcare officials and researchers. The registry contains nearly 6 million tests for 628,138 individuals over a 12-year period. The registry supports efforts to understand the epidemiology of STDs as well as health services and outcomes for those diagnosed with STDs. Specialized disease registries hold promise for collaboration across clinical and public health domains to improve surveillance efforts, reduce health disparities, and increase prevention efforts at the local level.

Sexually Transmitted Diseases; Registries; Public Health Informatics

Introduction

Sexually Transmitted Diseases (STDs)

Undiagnosed and untreated sexually transmitted disease (STD) is associated with adverse outcomes such as infertility, increased HIV transmission and acquisition, and adverse pregnancy outcomes. Several STD health services are recommended by the Centers for Disease Control and Prevention (CDC) to protect the reproductive and sexual health of young men and women. Recommendations include: annual chlamydia and gonorrhea screening of sexually active women ≤24 years, pregnant women, and older at-risk women; chlamydia and gonorrhea screening of anatomic sites of exposure (urethral, rectal, or pharyngeal) of men who have sex with men (MSM); retesting of all infected persons after treatment for chlamydia or gonorrhea; and syphilis testing of pregnant women as well as sexually active MSM [1].

Surveillance of STDs and STD Services

A core function of public health is the assessment of disease prevalence and burden as well as the utilization of health care services, also referred to as public health surveillance [2]. Ministries around the globe seek to perform surveillance on STDs as well as the utilization of STD health services. They further seek to monitor the quality of health services received by at-risk groups, assess adherence to recommendations for chlamydia and gonorrhea testing and retesting, syphilis testing, test results, patient and partner treatment, and the incidence of adverse outcomes related to STDs.

Assessing STD prevalence, burden and utilization of health services is challenging, because available data sources are limited by small sample sizes, incomplete demographic information, cross-sectional design, insufficient periods of follow-up time, and incomplete information about the services provided [3]. Access to a longitudinal data source with complete demographic and clinical information for individual patients is challenging for public health agencies and researchers, especially in the United States, given the fragmented delivery of care in public and private settings. Furthermore, there are even fewer data sources that capture an entire geographic community as opposed to a population defined by a single institution that provides care or insurance (such as a managed care population). While data sources such as population health surveys provide partial information, none have been able to provide all the information required to assess community access, utilization and quality of services, and the incidence of adverse outcomes following an STD.

Specialized Disease Registries

Centralized data registries have become important informatics tools for surveillance and research in a variety of public health contexts, including cancer treatment [4], immunization programmes [5], and injury prevention [6]. In fact, expanded health policies in the United States, referred to as “meaningful use” criteria for electronic health record (EHR) systems, include disease registries as a ‘public health’ criterion for the years 2013-2018 [7]. These policies encourage providers to submit patient-level information to specialized registries.

Once populated, disease registries can be reused for a variety of purposes, including clinical performance improvement, surveillance of disease incidence, and research on the utilization of health services [8; 9]. In essence, disease registries serve as integrated surveillance systems that support a wide range of clinical and public health functions.

Research Objective

Given the need for better community-level surveillance of STDs and STD health services as well as the past success of
other population disease registries, we sought to develop a longitudinal, comprehensive patient-centric registry to examine STDs and STD health services in a large metropolitan area. We hypothesized that the registry would support analysis of STDs and STD services as well as ongoing surveillance practice among public health agencies in that community.

Methods

We created a registry for all individuals tested for one of three STDs (chlamydia, gonorrhea, syphilis) between January 1, 2003, and December 31, 2014, by healthcare providers in the Indianapolis MSA (metropolitan statistical area). To create the registry, we gathered data from clinical and public health sources, linked individual patient records, and created a secure environment to facilitate collaborative access for surveillance and research. Our work occurred in partnership with local, state, and federal public health partners and was approved by the Institutional Review Board (IRB) at Indiana University.

Geography and Population Information

According to the 2010 census, Indiana ranked 15th among the states by population with just under 6.5 million residents. Consistent with national data, STDs are over-represented in racial and ethnic minorities (cases per 100,000 population). For example, the 2015 rate of gonorrhea among African Americans was 836 compared to the rate among Caucasian 87.7 and Hispanic individuals 85.0. The rates for chlamydia were 2234 for African Americans, 319 for Caucasians, and 545 for Hispanics for primary and secondary syphilis (26.8, 6.6 and 16.6, respectively).

The Indiana State Health Department (ISDH) STD Control Program divides the state’s 92 counties into ten districts for morbidity reporting and disease intervention purposes. These district offices are the recipients of contracts with the STD Program for the state’s approximately 30 disease intervention specialists. The Marion County Public Health Department (MCPHD) STD Control Program has responsibility for STD reporting in District 5, which includes Marion County (Indianapolis) and the seven surrounding counties: Boone, Hamilton, Hancock, Hendricks, Johnson, Morgan, and Shelby. This district makes up the majority of the Indiana MSA.

District 5 (population of 1.7 million) and Marion County (population of 903,393) account for the largest share of Indiana’s STD morbidity. In 2015, District 5 accounted for 39% of the state’s chlamydia morbidity, 47% of the state’s gonorrhea, and 60% of the state’s primary and secondary syphilis. This partially reflects the district’s racial health disparities, which is substantially more diverse than the state.

According to the CDC’s 2015 STD Surveillance Report, Indiana reported a total of 28,886 cases of chlamydia and ranked 27th among states in rate (437.9/100,000), while Marion County ranked 25th among United States counties and independent cities at 949.3 cases/100,000 population. Indiana ranked 23rd among states for gonorrhea with a case rate of 118.9/100,000 population, while Marion County ranked 16th among United States counties and independent cities in the rate of gonorrhea cases with 344.1 cases/100,000 population.

Residents of District 5 receive STD diagnostic and treatment services through the Bell Flower Clinic, the STD Control program of MCPHD, which also houses the District 5 reporting site. The program is operated by the Health and Hospital Corporation, which also operates MCPHD and safety net hospital for the county. The Bell Flower Clinic, therefore, serves those at highest risk. Of the unique patients at the Bell Flower Clinic, 57% were African-American, 33% were Caucasian, and 7% were other. Seven percent were Hispanic, mostly of Mexican descent.

Data Sources

Data for the registry came from three distinct sources:

1. The Indiana Network for Patient Care (INPC), a regional health information exchange (HIE) network that contains longitudinal EHRs for patients who received care in the Indianapolis MSA.
2. MCPHD Bell Flower Clinic, the STD Control Program which houses an information system where disease investigators enter details about STD cases reported to public health for the Indianapolis MSA.
3. MCPHD Birth Registry, a vital records information system used at MCPHD to capture data on all births in Marion County, in which Indianapolis is located.

Indiana Network for Patient Care

The INPC is one of the largest community-based HIE networks in the United States [10; 11]. The INPC connects over 90 healthcare facilities, including hospitals, physicians’ practices, pharmacy networks, long-term post-acute care facilities, laboratories, and radiology centers. The INPC maintains over five billion structured observations for over 12 million individuals; nearly one million electronic healthcare transactions are processed every day.

From the INPC, we extracted demographic data (e.g., gender, age, race, county of residence), STD laboratory testing data (e.g., lab test, date of test, result), co-morbidity data (e.g., pregnancy status, HIV status, ICD diagnoses) at time of STD test, encounter data (e.g., visit date, visit type), and medication history (e.g., drug name, drug class, date of dispense).

MCPHD Bell Flower Clinic and ISDH Morbidity Data

From the files at the Bell Flower Clinic, we extracted demographic data (e.g., gender, age, race), STD laboratory testing data (e.g., lab test, date of test, result), co-morbidity data (e.g., pregnancy status, HIV status) at time of the STD test, and medication information (e.g., drug name, drug class, date of dispense).

Because STD treatment may not be fully captured by the INPC, we extracted treatment of STD morbidity information.
from the ISDH reporting database, SWIMSS (Statewide Investigating, Monitoring and Surveillance System).

**MCPHD Birth Registry**

The MCPHD Birth Registry contains records on all live births in hospitals and birthing centers in Marion County as reported by birth registrars. From the birth registry, we extracted pregnancy outcomes (e.g., date of delivery, infant weight, gestational age), STD laboratory testing data (e.g., lab test, date of test, result), and co-morbidity data (e.g., HIV status) at time of delivery.

**Record Linkage, Integration, and Preparation**

Data were integrated from the three distinct sources using a two-step process (Figure 1). First, individuals were linked across datasets. Next, data from each source was extracted and combined into a single, patient-centric data registry.

The INPC employs an advanced, probabilistic matching algorithm that matches patient identities using first name, last name, social security number (when available), date of birth, phone number (when available), and gender [12]. The two MCPHD datasets were independently linked to the INPC using the enterprise master person index (eMPI), based on that algorithm. Individuals in the MCPHD STD Case and Morbidity Files who did not match to an INPC individual were imported into the registry as new clients. Only data for individuals in the MCPHD Birth Registry who matched an INPC individual were imported from the vital records system.

Once patient identities were linked, longitudinal data for each unique individual were extracted, transformed, and loaded from the three sources into the registry. Each unique individual was given a de-identified or pseudonymised “client ID” that did not resemble his/her medical record number or any identifiers in the MCPHD datasets. Birth dates were transformed to ages and other identifiable information was removed. The ability to re-identify individuals exists to enable capture of new and updated information using a key between the medical record number and the client ID. Only the data manager at Regenstrief can perform data updates. Registry users cannot access such details to ensure confidentiality of records.

**Data Management**

The deidentified, linked registry datasets are hosted on a secure, virtual server at the Regenstrief Institute (Figure 1). The encrypted server is password-protected and managed by the technical services division at Indiana University (IU). The datasets are stored as a collection of interoperable data files, enabling them to be interpreted by all major analytical software tools. The data files require 20GB disk space.

Authorized users include public health scientists at the CDC and MCPHD as well as scientists working at Regenstrief and IU. The virtual environment affords users the opportunity to leverage a wide range of analytical tools, including SAS, R, and SPSS. Analyses of the data can be performed within the IU high-performance computing environment without necessitating download of the data onto local computers or drives. Output from the analyses, such as tables, charts, and graphs, can be downloaded from the servers to support in public health or academic reports.

**Results**

The registry contained 5,093,863 STD tests for 628,138 unique individuals collected over a 12-year period. In Table 1, we present the demographics of the individuals who were tested and those who tested positive for an STD in comparison to the overall demographics for the Indianapolis MSA. Although the area was well-balanced with respect to gender, a greater proportion of females were tested for STDs. This is likely due to clinical guidelines that recommend screening pregnant women and young, sexually active women for STDs. African American individuals were proportionately tested more and had a greater proportion of disease, than other races. These data highlight both a racial disparity in disease burden as well as the fact that providers are more regularly screening this population.

In Figure 2, we summarize test results and positivity over time across all three STDs. Positivity is defined as the number of positive laboratory tests that confirm the presence of disease divided by the total number of lab tests analyzed. The overall volume of tests captured by the registry increased through 2011 then plateaued as result of the growth in the contributing data sources to the INPC from providers joining the HIE network to comply with ‘meaningful use’ incentives. Growth in the volume of data captured by the INPC resulted in decreased positivity; the number of negative tests grew by a factor of 3, while the number of positive tests increased by a factor of 2.5 (from 10,044 in 2003 to 25,606 in 2014). While the total number of positive STD cases grew dramatically, this growth is attributed to increased electronic lab reporting rather than an outbreak of disease.
Discussion

By integrating three disparate sources of routinely collected clinical and public health data, we have created a novel registry containing longitudinal data on individuals tested for STDs in a large metropolitan area. The STD registry is an important public health informatics resource as it affords surveillance and research on STD testing, services, and outcomes. While each data source may exist independently in states and nations around the world, very rarely are EHR systems, vital records, and STD morbidity files linked and used to examine those tested or treated for STDs.

Most often, health departments only have access to positive laboratory results, which are required by law to be reported to health authorities [13]. While electronic laboratory reporting of positive test results improves the completeness and timeliness of public health reporting [14; 15], the lack of negative test reporting prevents health departments from examining whether individuals at risk for STDs are receiving recommended screening. Moreover, while health departments maintain both STD morbidity and vital record information systems, many health departments fail to link these data to examine outcomes for pregnant women or populations at risk for poor birth outcomes. Therefore, integrating clinical and public health datasets allows for an expanded evaluation of preventative services, clinical guidelines, and outcomes experienced by those with STDs.

Our work demonstrates the feasibility of creating a specialized STD registry for conducting surveillance and research. Building the registry further highlights three lessons for the biomedical and public health informatics communities. First, specialized registries that cross clinical and public health boundaries can be created in a way that preserves privacy and confidentiality. Second, record linkage is a crucial aspect of creating a registry. Third, health IT policies affect the breadth and depth of specialized registries.

Maintaining Privacy and Confidentiality of Health Data

Individuals and health organizations can be fearful of centralized, monolithic databases that contain protected health information [16]. Therefore, healthcare providers may be wary of releasing identifiable information to public health authorities, except when required by law to do so.

To create our registry, we leveraged the Regenstrief Institute, a neutral third party with experience in protecting health data. Regenstrief is a business associate with healthcare providers, public health authorities, and the INPC [11]. As a convening, trusted partner, the Institute was able to bring clinical and public health organizations together to exchange identifiable data that could be linked and then de-identified for storage in a secure, common environment that affords surveillance and research by multiple users. The role of neutral third parties is supported by prior HIE research [17]; therefore, public health authorities should look to HIE networks or other third parties to support creating and maintaining specialized registries.

The Critical Role of Data Linkage

One of the most important and challenging aspects of creating the registry was record linkage. Linkage is important because uniquely identifying individuals is critical to pulling fragmented EHRs together for tracking an individual’s STD testing and services longitudinally.

Because the original data sources independently maintain distinct, unique identifiers for individuals and the United States lacks a universal health identifier, there was no easy method to link individuals at the start of the project. While the probabilistic algorithm used by the INPC’s eMPI is excellent, it is not flawless. Therefore, each public health source had to be independently matched to the INPC, and then the two matched sets had to be linked using a third round of matching. Due to the lack of universal identifiers, each round of matching involved some degree of manual review and a decision threshold for determining correct matches had to be established. The necessity of manual review prohibits automation and scaling of specialized registry creation.

One potential solution for others is a client registry (CR) [18]. A CR adjudicates identities across EHR and other data systems, like vital records and morbidity information systems, producing a centralized MPI to link identities across data sources. CRs have been demonstrated in HIE networks emerging in several countries, including Rwanda [19]. The CR should be further studied and applied to specialized disease registries.

Robust Policies Facilitate Specialized Registries

The STD registry is but one example of a specialized health data registry. While a wide range of registries for injuries, vaccines, and diabetes existed before the HITECH (Health Information Technology for Economic and Clinical Health) Act of 2009, the “meaningful use” program’s incentive for clinical providers to contribute data to a specialized registry encourages clinical-public health data exchange. Local health authorities struggle to receive data that are currently not covered under existing public health laws. While new laws can be written to require data exchange, health authorities have an opportunity to leverage existing policies, like HITECH, to work with clinical providers to create and sustain population health surveillance through specialized registries.

When creating registries, health authorities should consider the unique health needs of their jurisdiction. Community health assessments, an activity involving the gathering of input from a wide array of stakeholders on the important issues facing a community, are another opportunity to work with healthcare providers to identify key health issues that might benefit from a specialized disease registry. Diabetes may be a top priority in one nation, while hypertension might be a top priority in another jurisdiction. Working with healthcare providers to identify the health priorities of a community may lead to better participation in the registry as well as progress in “moving the needle” towards higher quality of care and outcomes for at-risk populations.
Future Directions for the STD Registry

The STD registry allows our team to explore many important questions relevant to public health practice and research. Our team is currently conducting the following analyses and plans to disseminate results in the coming year:

- **Utilization of STD Services**: Understanding where individuals present for STD services is critical for appropriately allocating available resources. Using the data available within the registry, we are examining testing locations and positivity rates of individuals to determine where individuals present for STD care and whether a positive result increases the likelihood of presenting to a specific location.

- **Testing and Outcomes for Pregnant Women**: Women should be screened and treated for STDs while pregnant. Using the available testing data for women who either tested positive for pregnancy or delivered a baby, we are examining the proportion who received an STD test; of those, which women were positive and the birth outcomes for women who tested positive.

In addition, we seek to expand the capacity for the registry to support other research and surveillance of STD testing, services, and outcomes. In the next year, we plan to link the registry to other unique public health datasets, including the Immigrant Tuberculosis and All Refugee Application (ITARA) database. This database includes information on Indiana state immigrant medical exams. Incorporating these data will facilitate an analysis of newly immigrated citizens for incidence as well as risk factors associated with STDs. The registry will continue to be hosted at Regenstrief for use by public health researchers as well as epidemiologists in local, state, and federal agencies.

Conclusion

Using multiple data sources, we successfully linked and integrated data relevant to the testing, treatment, and outcomes for individuals with STDs to create a specialized STD registry. Registries like this one are increasingly feasible to build using informatics approaches. Specialized disease registries are critical to understanding the epidemiology of disease and enable collaboration across clinical and public health domains to improve surveillance, reduce health disparities, improve health services for individuals with disease, and increase prevention efforts at the local level.

Development and Validation of Various Phenotyping Algorithms for Diabetes Mellitus Using Data from Electronic Health Records

Santiago Esteban, Manuel Rodríguez Tablado, Francisco Peper, Yamila S. Mahumud, Ricardo I. Ricci, Karin Kopitowski, Sergio Terrasa

Family and Community Medicine Division, Hospital Italiano, Buenos Aires, Argentina

Abstract

Precision medicine requires extremely large samples. Electronic health records (EHR) are thought to be a cost-effective source of data for that purpose. Phenotyping algorithms help reduce classification errors, making EHR a more reliable source of information for research. Four algorithm development strategies for classifying patients according to their diabetes status (diabetics; non-diabetics; inconclusive) were tested (one codes-only algorithm; one boolean algorithm, four statistical learning algorithms and six stacked generalization meta-learners). The best performing algorithms within each strategy were tested on the validation set. The stacked generalization algorithm yielded the highest Kappa coefficient value in the validation set (0.95 95% CI 0.91, 0.98). The implementation of these algorithms allows for the exploitation of data from thousands of patients accurately, greatly reducing the costs of contracting retrospective cohorts for research.

Keywords:
Diabetes Mellitus, Algorithms, Precision Medicine

Introduction

Recently, the progression towards precision medicine [1] has sought the development of large databases, allowing assessment of the impact of risk factors or treatments in specific subpopulations. This is usually a problem for classical cohorts, given the difficulty of enrollment and follow-up of a large enough number of patients [5]. Even more difficult is the situation for developing countries, given the usual lack of funds for local research [3].

Electronic health records (EHR) have been proposed as a solution to these two costs problems [10].

Phenotyping algorithms allow, through the combination of different variables extracted from the EHR, classifying patients according to their particular phenotype [8; 11]. Ideally, these algorithms must be validated and a metric should be estimated (accuracy, sensitivity and specificity, coefficient Kappa, F1 score, positive and negative predictive values) of the ability to classify patients compared to a gold standard. This facilitates the classification of large numbers of patients without the intervention of a human.

Boolean or rule-based algorithms are a common strategy for developing these algorithms. A different approach is the development of learners based on statistical learning, such as logistic regression or more recent methods such as decision trees, neural networks or support vector machines. The different families of algorithms explore the multidimensional space of data in different ways so it can be beneficial to combine them. One way to do this is through stacked generalization. This methodology, described by Wolpert [4] for classification problems and by Breiman [7] for regression problems, seeks to improve the predictive power of the individual algorithms by developing a meta-learner incorporating the predictions of all algorithms as input, combining them, and then issuing a final prediction.

Our objective is to compare the performance of different classification strategies (only using standardized problems, rules-based algorithms, statistical learning algorithms and stacked generalization), for the categorization of patients according to their diabetic status (diabetics, not diabetics and inconclusive; diabetes of any type) using information extracted from EHR.

Methods

Study population

Patient information was extracted from the EHR of the Hospital Italiano in Buenos Aires, Argentina.

In order to have a training and a validation dataset, two samples of patients from different years (2005-2015; total n = 2463) were extracted. The only inclusion criterion was age (≥40 <80 years old by 1/1/2005 and by 1/1/2015 for each sample). The sampling was carried out using simple randomization. The training set (2005) featured 1663 patients. The validation set (2015) represented roughly 33% of the total sample (n = 800).

Feature extraction

Six variables were extracted: No. of standardized problems related to Diabetes Mellitus (DM) (inpatient, outpatient and emergency department codes); No. of filled oral hypoglycaemic or insulin prescriptions; No. of outpatient fasting glucose (FG) measurements ≥126 mg/dl; No. of outpatient FG measurements <126 mg/dl; No. of HbA1c measurements ≥6.5%; No. of HbA1c measurements <6.5%. These variables were also used in previous research [6; 12]. Oral glucose tolerance measurements were left out in order to avoid making a diagnosis of gestational diabetes. Random ≥200 mg/dl blood glucose was not considered since it was difficult to establish if it coincided with diabetic symptoms, as indicated by the criteria of the American Diabetes Association (ADA).
Manual chart review

Four researchers manually reviewed all records and classified patients, analyzing all available information in the EHR. Patients were classified as:

- Diabetics: The ADA criteria [2] to classify patients as diabetics were used. Also, patients whose records stated that they were diabetics were classified as such.
- Not diabetic: To be classified as a non-diabetic, patients must have at least one FG measurement below 126 mg/dl, and must not have any references in their records regarding being diabetic or fulfill any of the ADA’s criteria for DM.
- Inconclusive: Patients without a reference in their EHR regarding their diabetic status, nor a normal FG measurement, were classified as inconclusive. Those who had a single FG value above 126 mg/dl without a subsequent confirmatory measurement were characterized in the same way.

The level of agreement among researchers was assessed using the Kappa coefficient with a value of 0.92 (95% CI: 0.84, 0.99).

Algorithm development and validation process

![Figure 1 - General process of developing and validating phenotyping algorithms. EMR: Electronic Medical Records](image)

Rules-based algorithms

In our study, we included two algorithms of this type:

- Classification of patients according to standardized codes: patients were classified as diabetics if they had at least one DM code in their EHR.
- Boolean logic algorithm (Adapted from Kho, Wilke, and Nichols): we used a combination of these three algorithms.

Algorithms based on statistical learning

Four of these learners were included individually: multinomial logistic regression, random forests, neural networks and support vector machines with radial kernel. According to their performance on the test set, the best one was evaluated in the validation set.

The problem of imbalanced datasets

We opted to use sampling techniques to adjust the imbalance between classes of the dependent variable. To select the best synthetic sampling algorithm, we divided the derivation dataset into a training and a test set. We then used the approach developed by Lopez et al. [9]: from the training set, we generated 19 sets of data by applying a combination of over and under sampling algorithms and analyzed them by means of four algorithms that use different approaches (neural networks, Elastic Net, Gradient Boosting Machine and C5.0). We then applied the trained learners on the test set (which remained unbalanced) and then ranked the datasets according to their performance. The best ranked dataset was used for the training of the statistical learning algorithms.

Development of the meta-learner

For the final prediction we selected the Elastic-Net algorithm. As a first step, we discarded those learners with significantly lower performance in the different subsets of the repeated cross-validation (RCV) (set 1). Then, four selection strategies were used: 1. We kept those algorithms whose performance in the different subsets of the RCV were less correlated (Pearson coefficient <0.75; set 2); 2. Using hierarchical clustering (Euclidean distance, complete method), learners were clustered according to their patterns of performance in the subsets of the RCV; the best within each cluster at different height levels were selected (sets 3, 4, 5); 3. We selected those with better performance within each family of algorithms (support vector machines, neural networks, decision trees, instance-based algorithms, algorithms, Bayesian, discriminant analysis, and linear models (set 6). Each of these versions of the meta-learner was evaluated on the test set and the most parsimonious and best performing learner was selected as the final model.

Validation

For the validation process, the different algorithms were evaluated in the validation set. The Kappa coefficient was used as the performance metric.

All analyses were performed using R (R Foundation for Statistical Computing, Vienna, Austria.) URL: https://www.R-project.org).

Results

Table 1 shows the characteristics of the patients included in both datasets. We can observe that patients from the sample of 2015 (validation dataset) generally have a greater number of measurements.

![Table 1 - Characteristics of patients included in the training and validation datasets. DM: Diabetes Mellitus; FG: Fasting glucose](image)
The results of all proposed algorithms are presented in figure 2 and table 2.

Development and selection of the synthetic dataset

The dataset with best performance was a combination of Synthetic Minority Over-Sampling Technique (SMOTE) and Edited Nearest Neighbors (ENN) and was selected for the training of models. See figure 3.

Algorithms based on statistical learning

The network neural presented the best performance in the test set and therefore was evaluated in the validations set (figure 2 and table 2).

Development of the meta-learner

Selection of models with the best performance

Figure 4 shows the performance of the 16 algorithms under consideration for building the meta-learner. Five algorithms showed Kappa coefficient values clearly below the rest and were excluded. The remaining eleven constitute set 1.

Selection of models based on low correlation

We assessed the level of correlation of performance of the algorithms in the different subsets of RCV (set 1). We detected those correlations greater than 0.75; then the average correlation of both algorithms were compared and the one with the highest mean correlations with all other models was removed. RRF, GBM, EGB - Linear and Elastic Net were removed. The remaining six formed set 2. The results are presented in figure and table 2.

Figure 4 - Algorithm performance averaged over 50 cross-validation training subsets. RF: Random forests; svmRadial: Support vector machines with radial kernel; GBM: Gradient boosting machine; EGB: Extreme gradient boosting; k-NN: k nearest neighbors; RRF: Regularized gradient forests; MLR: Multinomial logistic regression; NB: Naïve bayes; NSC: Nearest shrunken centroids; PLS: Partial least squares; PDA: Partial discriminant analysis; LDA: Linear discriminant analysis.
Selection based on hierarchical clustering

Figure 5 shows the dendrogram generated from the hierarchical clustering of the performance of the different algorithms in the subsets of RCV. Three cutoff points were chosen. For cutoff level, the algorithm with best performance by cluster was selected (Set 3: RF, svmRadial, k-NN, GBM; Set 4: 3 Set + MLR; 5 set: Set 4 + Neural Net, EGB - Linear). Each set was then used as input for a different version of the Elastic Net-based meta-learner. Each version was tested in the test set. Set 4 presented the best combination of performance and parsimony and was selected to be applied to the validation set.

![Figure 5 - Hierarchical clustering of classification algorithms based on their performance in the CV datasets.](image)

Selection based on algorithm family

We selected those algorithms with the best performance within each family, to form set 6 (SVM radial Kernel, neural network with a single layer, EGB - Linear, Random Forests and k-Nearest Neighbors).

Selection of the best meta-learner

Finally we compared the performance of different versions of the meta-learner in the test set. The version that used set 4 as input presented the best combination of performance and parsimony. Its ability to classify patients was then evaluated in the validation set (figure 2 and table 2).

Discussion

Three of the four algorithms evaluated on the validation set showed excellent performance in terms of the Kappa coefficient. Our decision to use this metric above others more commonly used, such as accuracy, was related to the need for high levels of classification within each of the categories given the imbalance of classes in our dataset. This can be affected when the considered metric is accuracy, since it does not consider the agreement for each class but only the level of total error in the confusion matrix.

Each strategy presents pros and cons that are important to consider, since performance is not the only variable to take into account when selecting an algorithm to apply. Algorithms based on rules have the advantage of being simple and easily scalable with minimum processing time. However, we found that their performance is clearly lower than those based on statistical learning and stacked generalization. The neural network showed a high level of optimism (the difference in performance between the training and the validation set). This was less significant for the stacked generalization, which would go in hand with the main objective of this strategy — to reduce overfitting to the training set. The version of the meta-learner that used set 4 as input showed the best metrics of classification in the validation set. Its implementation for research would be helpful, but probably not so for real-time applications given the higher processing time compared to simpler approaches.

Conclusion

We evaluated the performance of different strategies for the development of diabetes phenotyping algorithms using data extracted from an EHR from Argentina. The stacked generalization strategy showed the best metrics of classification in the validation set. The implementation of these algorithms enables the exploitation of the data of thousands of patients accurately, and a reduction of costs compared to traditional ways of collecting data for research. Thus, millions of patients from developing countries could benefit from local and specific data that could lead to treatments that take into account all their characteristics (genetic, environmental, habits, etc.) as it is the objective of precision medicine.

Abstract

Drug and supplement interactions (DSIs) have drawn widespread attention due to their potential to affect therapeutic response and adverse event risk. Electronic health records provide a valuable source where the signals of DSIs can be identified and characterized. We detected signals of interactions between warfarin and seven dietary supplements, viz., alfalfa, garlic, ginger, ginkgo, ginseng, St. John’s Wort, and Vitamin E by analyzing structured clinical data and unstructured clinical notes from the University of Minnesota Clinical Data Repository. A machine learning-based natural language processing module was further developed to classify supplement use status and applied to filter out irrelevant clinical notes. Cox proportional hazards models were fitted, controlling for a set of confounding factors: age, gender, and Charlson Index of Comorbidity. There was a statistically significant association of warfarin concurrently used with supplements which can potentially increase the risk of adverse events, such as gastrointestinal bleeding.

Electronic Health Records; Natural Language Processing; Warfarin

Introduction

Drug and supplement interactions (DSIs) have drawn widespread attention in recent years due to the increased prevalence of dietary supplements worldwide. Patients often take prescribed medications along with dietary supplements to boost the immune system or to mitigate the side effects of a particular treatment. A major safety concern is the potential for dangerous adverse events caused by DSIs, particularly for drugs with narrow therapeutic indexes, such as warfarin. Increasing our knowledge base about DSIs will assist pharmacists and healthcare providers to provide guidance to patients on the safety and efficacy of the concomitant use of prescribed medications and dietary supplements, especially for the elderly, who have increased vulnerability to DSIs. Given the difficulty of testing DSIs in human populations, information on DSIs mostly comes from \textit{in vitro}, animal research, or case reports [1]. Unfortunately, this information is under-reported and can be inconsistent. Also, clinical trials for drug approval may not reveal DSIs since supplements and drug-drug interactions often require large patient populations for adequate study power, especially with rare events. Our prior study identified several known and potential DSIs by mining 23 million biomedical literature abstracts (MEDLINE) [2]. Although the biomedical literature may help us to infer DSI knowledge and potential hypotheses for novel DSIs, we may also leverage electronic health record (EHR) systems to complement DSI understanding and validate DSI hypotheses. EHRs offer a rich source of patient information since they serve as the primary patient care documentation platform for clinical care delivery. Some EHR data of interest to study DSIs include medication information, problem lists, laboratory data, and clinical notes. Warfarin, as one of the most commonly prescribed anticoagulants, is widely used to treat and prevent thromboembolic events associated with atrial fibrillation, heart valve replacement, myocardial infarction and existing thromboembolic disease. However, warfarin is often involved in interactions with supplements because its metabolism involves multiple active metabolic pathways [3]. Natural products such as garlic, ginger and ginkgo are among the most common supplements implicated in DSIs with warfarin. Garlic has the side effect of platelet inhibition, which can increase the risk of bleeding when used with anticoagulant drugs [4]. Ginger can inhibit thromboxane synthetase and therefore lead to prolonged bleeding times [4]. Ginkgo will increase the International Normalized Ratio (INR) with warfarin, and ginseng might reduce the effect of warfarin [4]. Vitamin E can interact with warfarin due to blood thinning effects, especially in Vitamin K deficient individuals [5]. According to the Natural Medicines Comprehensive Database (NMCD) [6], warfarin also has significant interactions with alfalfa, grapefruit, and St. John’s Wort.

In our previous study, we found that clinical notes contain some supplement mentions that do not exist in the medication list [7]. Much information about supplement use is embedded in clinical notes, and thus in this study we demonstrate that informatics techniques, especially natural language processing (NLP) methods, are effective in extracting supplement use status information from clinical notes. Specifically, we conducted survival analysis to test the significance of the concomitant use of warfarin and supplements associated with the appearance of adverse events based on the EHR data from University of Minnesota Clinical Data Repository (UMN-CDR). We focused our assessment on the adverse interactions of warfarin with seven dietary supplements: alfalfa, garlic, ginger, ginkgo, ginseng, Vitamin E, and St. John’s Wort, with potential interactions indicated in the NMCD knowledge base. Adverse events associated with atrial fibrillation, heart valve replacement, myocardial infarction and existing thromboembolic disease. However, warfarin is often involved in interactions with supplements because its metabolism involves multiple active metabolic pathways [3]. Natural products such as garlic, ginger and ginkgo are among the most common supplements implicated in DSIs with warfarin. Background

Warfarin potential interactions

Warfarin is a medication with a long history of clinical use due to its effect on the human coagulation system, but also as a poisoning agent/rodenticide due to these same pharmacologic characteristics. This dichotomy is carefully balanced clinically by having regular testing of the therapeutic response with the use of warfarin. Patient monitoring is managed by assessing blood coagulation with prothrombin times and INR testing which provide standard clotting measures. The testing is typically done on a monthly basis or even more frequently with substantial dosage changes or use of medications associated with drug-drug interactions. This intensive follow-up therapy helps to reduce the clinical risk of excess therapeutic effect (anti-coagulation) which can result in bleeding. In addition, the monitoring allows dosages to be constantly adjusted to maintain adequate levels of anti-coagulation to prevent thromboembolic events. Given this frequent follow-up by patients, the shifts in levels of anti-coagulation are typically noticed before clinically significant events occur. However, if patients initiate new medications or supplements shortly after regular testing, they may be at risk for several weeks before routine testing can detect drug responses outside of the usual therapeutic range.

BioMedICUS and NLP-PIER

Both BioMedICUS and NLP-PIER are tools developed by the NLP/Information Extraction group at the UMN. BioMedICUS (Biomedical Information Collection and Understanding System) [8] is an open-source NLP system based on the Unstructured Information Management Architecture Asynchronous Scaleout (UIMA-AS) architecture [9] specializing in NLP-related information extraction and understanding of clinical notes. NLP-PIER (Patient Information Extraction for Researchers) is a web-based search engine for clinical notes from the EHR [10]. Clinical notes in the CDR are run through a BioMedICUS NLP pipeline and indexed for use in NLP-PIER. BioMedICUS identifies UMLS Metathesaurus concepts (concept unique identifiers, or CUIs) from lexical variants expressed in the notes, and whether the identified concepts were used in a negated context. These negation-qualified CUIs are added to a set of 15 patient-related and encounter-related note attributes from the CDR, including five attributes from the HL7-LOINC document ontology [11]. Attributes and CUIs are stored in an Elasticsearch cluster along with the clinical note itself, which is run through an Elasticsearch snowball analyzer when it is indexed. This setup enables full text searches to be run on research-related note sets within NLP-PIER. Search terms can be expanded by specifying UMLS CUIs as part of the search query and results can be filtered using the attributes.

Methods

The method of this study consists of five steps: 1) data collection: search for patients taking warfarin and collect information about patients’ demographics, warfarin usage, diagnosis and clinical notes; 2) NLP for supplement information extraction: apply NLP module to extract information about supplement use in clinical notes; 3) structured data query: query medication table for supplement use and diagnosis table for adverse events; 4) data combination: combine information from structured and unstructured data to generate a comprehensive data set for each patient; 5) statistical analysis: conduct survival analysis to detect the significance of adverse events caused by concurrent use of warfarin and supplements.

Data collection

Patient cohort data in the Epic EHR were extracted from the UMN-CDR hosted by the Academic Health Center-Information Services (AHC-IS) exchange platform and supported through the Clinical Translational Science Institute (CTSI) at the UMN. The data in the CDR comes from the EHR of more than 2 million patients who sought health services at eight hospitals and over 40 clinics. Data are available for hospital visits starting from 2011. IRB approval was obtained for accessing the clinical notes.

Patients who have warfarin prescriptions from 2011 to September 2015 were included by using both generic name and brand names (i.e., Coumadin, Panwarfin, Sofarin) of warfarin. Patients with medication records showing at least one warfarin prescription and complete information about the warfarin start date and end date were included in this study. The data from a total of 48,426 patients were stored in AHC-IS data shelter, which included patients’ demographic information, diagnosis, and medications. Clinical comorbidities were calculated using the Charlson Index of Comorbidity. Their corresponding clinical notes were processed by BioMedICUS and indexed by NLP-PIER for further information extraction.

NLP for supplement information extraction

Since much of the information about supplement use was embedded in clinical notes, we retrieved the related clinical notes using PIER for further information extraction. Selected supplements and all their lexical variants were used for retrieving clinical notes. For instance, “gingko”, “Vitamin E” and “St. John’s Wort” have their lexical variants including “gingko”, “ginko” and “ginkoba”, “Vit E”, “St. Johns Wort”, “St. John Wort”, “St John Wort”, “St Johns wort”, “St Johns wort”, “St John Wort”, respectively. However, we found instances of negative mentions (such as discontinuation of supplements) in the notes, such as “she may try ginkgo biloba for her memory issues” or “Denies using St John’s Wort”. Therefore, we applied a NLP module to classify the use status of the supplements, especially the active ones, such as “started” and “continuing”, and also filtered the irrelevant clinical notes, such as “discontinuing” and negative mentions.

In our prior study [12], we used machine learning-based methods to automatically classify the use status of the supplements into four categories (Continuing (C), Discontinued (D), Started (S), Unclassified (U)). A total of 1,300 sentences on 25 most commonly consumed supplements were randomly selected and annotated. The training set consisting of 1,000 sentences of 10 supplements was used to select the optimal algorithm with the identified feature sets. The test set included 300 sentences on the remaining 15 supplements. We trained four algorithms with seven different feature sets in the study. The best model (i.e., Support Vector Machine (SVM) with the feature set of unigram, bigram and indicator words within window size of four tokens on both sides of supplement mention) achieved F-measure of 0.906, 0.913, 0.914, 0.715 for status C, D, S, U on the test set, respectively. We further applied the trained SVM model on the notes retrieved in this study. We only consider the “Continuing” and “Started” categories since they are the active status for supplement use. “Discontinued” category may hold important information about the past use of supplements, however, the start date of the supplements remains unclear, therefore, “Discontinued” was considered negative case in this study.
effect bias, the first 30 days of warfarin use were eliminated when any of the supplements were first noted in the EHR after eliminating the first 30 days of warfarin use. For the warfarin-only group, day 1 was actually the day 31 for the warfarin use.

Survival analysis

Cox proportional hazards models were fitted to compare the hazard of adverse events between two groups, controlling for a set of confounding factors including age, gender, and comorbidities. All the patients were followed for one year for the first occurrence of adverse events. Follow-up ended with the first adverse event, or the end of the warfarin therapy. Kaplan-Meier survival curves were also plotted.

Results

A total of 41,257 patients were included in the study, among which 2,640 subjects were in the supplements-reported group who took warfarin and at least one of the seven supplements concurrently. The control group included 38,617 subjects in the warfarin-only exposures.

The number of patients taking each of the seven supplements were counted based on the information from both structured and unstructured data. The results in Table 2 indicate that the identification of supplement use was much larger with the use of the combination of structured and unstructured data approach, especially for garlic and ginger, since much of the information about dietary supplements related to food such as “garlic bread” and “ginger tea” were detected by our NLP module.

The hazard ratio, 95% CI, and p-value for the four adverse events are listed in Table 3. The results show that the hazard ratio of the four adverse events in the supplements-reported group are statistically significant and higher in the supplement exposed patients when compared with the warfarin-only group. The results indicate taking warfarin concurrently with supplements is associated with side effects such as bleeding, or therapeutic failure events like embolic stroke.

The Kaplan-Meier survival curves for four adverse events were shown in Figure 1. The results of the log-rank test indicate the survival curves for the supplements-reported group and the warfarin-only group are significantly different (P<0.01) in GI bleeding, general bleeding, and embolic stroke, however, for thromboembolism, there is no significant difference in the curves between the supplements-reported and warfarin-only exposure groups.

group and warfarin-only group.

Discussion

The literature has shown there may be potential adverse interactions between warfarin and supplements, however, in many cases, the limited available data impedes the assessment of the potential risk associated with concurrent use. Additionally, the data is hard to detect in clinical trials due to limited sample sizes and high costs for the evaluations.

Due to its blood thinning effect, patients on warfarin are warned to be careful taking other supplements, such as ginkgo, ginger, Vitamin E, which can potentially increase the risk of bleeding events. Our confirmation of these potential adverse interactions provides evidence to support the current clinical guidance and provides data to assess drug safety with DSIs. For example, alfalfa contains a large amount of Vitamin K, which can reduce the anticoagulant activity of warfarin [14]. Alfalfa was part of the original research on Vitamin K metabolism and was one of the first substances on which Vitamin K was synthesized. This finding is consistent with the expected response with Vitamin K directly reversing the effects of warfarin. Taking St. John’s Wort induces cytochrome P450 2C19 which may clinically affect warfarin [15]. Ginkgo also affects the CYP3A4 path by inducing the enzyme which may affect the R-enantiomer of warfarin [16].

This study demonstrates the feasibility of using clinical data from EHR to detect the signals for adverse events associated with drug and supplement interactions. The results of the study as noted in the hazard ratio indicate a higher risk of adverse events and therapeutic failure well beyond typical screening triggers to assess the signal for potential adverse events. Additional assessment of the clinical cases will be needed to confirm the temporal and pharmacological patterns with the results to better assess the risk of exposure to supplements. However, from a medication safety perspective, the approach substantially reduces the assessment effort by patient safety officers or clinician managers to identify potential drug safety issues.

Though we used structured data for our outcomes assessment, our results provide support for the use of unstructured data to assess clinical exposures and outcomes. In addition, the combination of structured data (i.e., structured medication table) with unstructured data (i.e., clinical notes) in identifying supplements use has shown that clinical notes contain valuable information related to supplements which can complement structured data for DSI detection in the EHR. It is noted from our study that very little information about supplements is stored in the medication table since dietary supplements are regulated as food and can be obtained over the counter without a prescription, consequently, much of the information about supplement consumption is documented in clinical notes during the medical encounter. Therefore, the combination of text information with a structured medication module is necessary for the supplements use identification, where NLP is essential for extracting supplements use related information from clinical notes.

One limitation of the study is that for some patients, the actual start date of supplements is before the date of the clinical note because we found some patterns like ‘she has started ginger two months ago’, which could lead to misclassification of the exposure in the statistical analysis. The data has limitations on both the medication and supplement orders, which limits the ability to directly assess the association between exposures and clinical outcomes. Correlation of these results with other peripheral data sources such as retail data, if available, could help better identify the acquisition of supplements for presumed use by patients. Patient diaries, medication adherence apps and other sources could also be considered as part of usual care processes to better identify supplement use.
The second limitation is that we only applied a limited set of common names of supplements in the search for notes related to supplement use which may have missed some supplement information. The recall of supplement information might be increased when using more complete supplement terms.

Another limitation of the study is that we did not take into consideration the end date of the supplements since this information was often missing. Such information may also be contained in the clinical notes but requires additional analysis. Future work including the development of the NLP system to accurately extract temporal supplement information from the clinical notes could better assess the relationships of supplement exposures to medication use and clinical outcomes.

Conclusion

This study indicates that it is possible to use existing EHR data to detect signals of DSIs. The current findings also demonstrate the feasibility of applying NLP methods to extract supplement usage information from clinical notes. Furthermore, these methods can likely be extended to detect other potential drug and supplement interactions providing an important approach for post-market surveillance for DSI as well as drug-drug interactions.

¹Department of Internal Medicine, Heidelberg University Hospital, Heidelberg, Germany

Abstract

Although sequencing technology has become widely available in recent years, the steps in bioinformatics pipelines are time-consuming and barely standardized. New tools to improve individual steps in a pipeline are frequently published and configurations can be quickly adapted to new versions. We performed case studies with a representative set of pipeline management tools using the GEP-R pipeline, and a qualitative study of different software packages covering relevant classes of software tools. We use a software toolset of R environment, Docker, KNIME, and BPEL to review our first aim of technical and organizational challenges. We propose snapshotting, documentation management, and a hybrid approach for our second aim of approaches to reproducibility. In order to have fully reproducible results derived from raw data, we think that it is necessary to archive biomedical analysis pipelines and their necessary software components.

Keywords:
Medical Informatics; Computational Biology; Software

Introduction

Sequencing and analysis of genomic data have become valuable technologies in both research and clinical settings. An effective and rapid analysis of data can support the identification of target genes and decision-making on diagnosis and treatment options [1]. Sequencing technology has become relatively cheap and widely available. In contrast, the steps of bioinformatics analysis following sequencing are still time-consuming and barely standardized. Typically, bioinformatics facilities develop and maintain their own chain of analytical steps, also known as an analytical pipeline. A variety of computer programs are available for each step. They have specific characteristics that make them more or less suitable for an analysis target. Each program used in each analytical step generates output data that can be used as input for the next program in the analytical pipeline. Since new tools for improving individual steps of a pipeline are frequently published, pipeline configurations can be quickly adapted to make use of the new versions.

Management of bioinformatics pipelines is facilitated by tools used for tasks such as the execution of serial and parallel steps and handling complex dependencies, varied software, data file types, and fixed and user-defined parameters [2]. Selection of tools in the pipeline depends on user requirement and implementation setting. Unfortunately, newer versions of packages can lead to unintended side effects in the analytical pipeline that may cause different results in calculations. Even small changes, like handling decimal places differently, can eventually lead to changes in classification of data or decision-making.

The problem of changing pipeline components is intensified by modular software packages such as the statistical software R [3]. Typically, a certain function is encapsulated into a package. However, packages often make use of functions provided by other packages, with each package having its own update cycle. As a consequence, complex packages have a complex dependency tree and are common in bioinformatics.

The differences in the pipeline implementation and frequent changes in tools and their versions affect the system’s stability, reproducibility, and validation. For example, a change in risk-classification software as mentioned above might lead to attribution to a different prognostic group for a patient. In such a case, problems occur when results are compared to those of other patients classified on different versions or if procedures are repeated on different versions. Consequently, technical and organizational steps are necessary to manage documentation, ensure version control, and validate pipeline configurations in a clinical setting.

Standardization and validation of the software tools are strong requirements for pipelines used in clinical implementation [4]. Thus, we propose two approaches for achieving reproducible pipelines: Snapshotting complete configurations, and documenting pipelines in detail.

Snapshotting

Taking a snapshot of a pipeline can be compared to freezing the whole runtime environment including all software components as they are installed at the time of taking the snapshot. The snapshot can be conserved for later reactivation or be transferred to another environment to replicate the pipeline. The environment can be built in a very interactive way, which makes it easy to implement even complex dependencies with heterogeneous version requirements. For example, the latest version of a certain package might depend on an older version of another package and hence it may not be possible to simply use the latest versions of all packages.

Pipeline documentation

Another way to conserve the pipeline configuration is to document the precise pipeline configuration. Preferably, this is done in a machine-readable way, so the pipeline can be rebuilt automatically. This approach relies on the software management capabilities of the programs used in the pipeline: they should support unattended installation methods in order to install the correct programs reliably. For modular software like R, functions have to be provided to extract the list of installed packages with versions and automatically reinstall the software from such a list.

A bioinformatics pipeline has been developed for a project called “clinically applicable, omics-based assessment of survival, side effects, and targets in multiple myeloma (CLIOMMICS)” during the research stage. It has further ma-
tured for use in clinical routine care. Multiple myeloma is a malignant disease characterized by molecular heterogeneity that can be assessed by gene expression profiling (GEP). The GEP-R is a reporting tool developed using R [3] and Bioconductor [5] and generates a medical letter summarizing the scores derived from the GEP analysis. Thus, it allows the automated interpretation of Affymetrix gene expression microarray profiles by using a bioinformatics pipeline. It aims to provide quality controlled, validated, and clinically digestible information that includes molecular classification, risk stratification, and assessment of target gene expression [2]. The result of the GEP-R bioinformatics pipeline is a report in the form of a letter to the physician in charge of patient treatment.

The aim of this paper is to describe the technical and organizational challenges of handling changes for bioinformatics pipelines, using the GEP-R project as an example. In addition, we propose two approaches to improve stability and reproducibility of the pipeline, as well as validity of its tools.

Methods

To investigate the possibilities for increasing reproducibility of bioinformatics pipelines we performed case studies with a representative set of pipeline management tools. We selected the software tools with the intention to cover the reproducibility strategies of pipeline documentation and pipeline snapshot. We do not aim to provide a comprehensive overview of pipeline management software found in Leipzig, and Curcin et al. [6, 7]; instead, we performed a qualitative study of different software packages covering relevant classes of software tools. These classes are:

- Package-based analysis software
- Virtualization software
- Graphical pipeline management software
- Document-oriented pipeline management software

We used the GEP-R pipeline as a test case.

GEP-R pipeline

The biomedical objectives of this pipeline are described in the original publication by Meissner et al. [2]. GEP-R is a typical pipeline for the analysis of DNA microarray data from a technical perspective. Specifically, .CEL files derived from Affymetrix U133 Plus 2.0 DNA microarrays are analyzed to classify stage, prognosis, and treatment options for patients with multiple myeloma. The pipeline consists of a series of Bioconductor functions to preprocess the raw microarray data and subsequently calculate relevant scores. In addition, quality control indicators are calculated. All results are combined and visualized in a format that can easily be interpreted by physicians by using the Business Intelligence and Reporting Tools (BIRT) framework [8]. The pipeline uses standard packages from R and Bioconductor repositories, and in addition, a modified non-standard version of a specific package is required. A workflow representation of the pipeline components is shown in Figure 1.

Software reviewed

Since R (often in combination with Bioconductor) is a very common pipeline component and at the same time a very complex system with complex internal dependencies, we consider it as a mandatory element of our test cases. Microsoft R repository is an approach for installing historic versions of R packages. It is possible to choose any date beginning 2014-09-17 within this repository and re-install a consistent R system based on package versions that were current on a specific date.

We chose KNIME Server version 4.3.2 [9] for a graphical pipeline management system for our test case. This tool has capabilities to interact with R and other external tools. The pipeline is manipulated as workflows via a graphical user interface. Workflows can be versioned and stored in a central repository.

We used Docker as a generic tool for preserving specific configurations of dependent software. With Docker, configurations can also be versioned and stored in repositories. In contrast to a pipeline management tool like KNIME, Docker cannot be used to provide a workflow by itself.

Finally, we investigated a document-oriented workflow management approach. BPEL can be used to design a workflow within the pipeline by describing its components with XML and Web Services. Changes in the pipeline can be tracked with version control and provide support for documentation management.

We performed our case studies on the basis of the bioinformatics pipeline established for the GEP-R report [2].

Results

The results are structured according to the research aims of our study. First, we describe the results for the evaluation of technical and organizational challenges. Second, we show our approaches for achieving reproducible pipelines by combining appropriate software components.

Aim 1: Technical and organizational challenges

R environment

R is a statistical software package that is very popular in biomedical research. However, its full scope cannot be leveraged by the monolithic core software, but relies on a huge amount of additional packages. R packages are typically developed by independent programmers and can be shared via the CRAN
network. As a result, release cycles of packages differ greatly and are typically not synchronized with the release cycle of core R. Since the behavior of packages can change during updates without notice, a newer version might break the pipeline.

The challenge of changing packages is attenuated to some extent by the R package checkpoint. This package was developed by Microsoft and allows rebuilding a consistent R environment using the Microsoft R Application Network (MRAN) repository. Unfortunately, it is not always the case that all packages used for a bioinformatics pipeline are at their current versions, since individual packages might have been added during the development process without updating the remaining packages.

In addition, bioinformatics applications are typically based on the Bioconductor tools. Bioconductor consists of more than 1200 R packages provided via its own repository system Bioc. Since Bioc is not included into the MRAN snapshots, it can be challenging if older versions of Bioconductor packages have to be installed manually.

**Docker**

Docker is an open source virtualization software that is installed on top of a variety of computer operating systems. It aims to virtualize individual applications in contrast to common virtualization approaches that work on complete computers. Docker provides mechanisms for easily moving the virtualized application (VA) between physical computers. The configuration of the VA can be versioned using the built-in snapshotting tool.

We successfully configured the complete R including Bioconductor and custom R packages inside a Docker container. This container can be copied to any computer that is intended for running our pipeline. Since the VA includes all required packages, we ensure consistent pipeline results across all instances. The integrity of the container is verified by comparing checksums of the VA’s snapshot.

**Graphical pipeline management system (KNIME)**

KNIME is a general-purpose data analytics tool that provides a user interface for preparing a specific pipeline by graphically combining predefined components called nodes. For many analytical steps that typically occur in bioinformatics pipelines, nodes are shipped with KNIME or can be installed from an additional repository. However, not all specialized functions of Bioconductor are natively available in KNIME. Access to Bioconductor functions is available via KNIME’s special R-nodes. These nodes are used for seamless integration of R-programs into KNIME workflows. Thus, data can be pre-processed in KNIME and R functions can be invoked as necessary within a workflow. The KNIME Server that we used for this test includes repository for storing and versioning pipeline configurations.

**Document oriented pipeline management (BPEL)**

The Business Process Execution Language for Web Services known as BPEL [10] is a process execution language standardized by OASIS. It allows the design of workflows using Web Services and represents data with XML specifications. Workflows can be linked and invoked by other Web Services, while inputs and outputs are assigned to variables to store data. Tools and technologies can be developed using Web Services to increase the level of automation in a process. Control structures used to manage tasks use either constructs that implement conditional branching and looping or activity containers to schedule sequential or parallel tasks. The capabilities of BPEL can be used for documentation management by describing the workflow of a pipeline with XML and tracking changes with its support for version control.

The GEP-R pipeline components can be described by expressing the exchanged data between the analytical steps as XML forms and by defining the order in which the Web Services are invoked. The steps in a process are known as activities and different methods can be used to manipulate data in the pipeline, such as invoking services, initializing variables, assigning values, and performing calculations. These can be combined into algorithms to perform complex processes. Changes in the pipeline can evolve and different versions can be deployed depending on the specific needs by using version control. Support for flexibility and adaptability to changes mitigate technical and organizational challenges and also simplify the process of documentation management.

**Aim 2: Approaches for reproducibility**

**Snapshotting**

Snapshotting seems to be the approach that is easier to implement since it is usually not disruptive to established development and implementation procedures. The granularity of scope that is covered by a snapshot depends on the software tools that are used. One approach is to cover complex components like R with Bioconductor. We established a Docker container that contained all specific configurations for our GEP-R pipeline. Since we were able to use the common interactive mode of installation, setting up the image for this container was relatively easy. Since the installation of packages is not limited to repositories, it was possible to compile and install a specifically modified R package into the container. When problems occurred during the installation process, it was possible to fix them without reinstalling the container as a whole. Since the latest snapshot covers all changes that were made to the container, it is hard to forget to document modifications as long as the snapshot is generated. Docker supports the development process by providing a versioning system that allows for multiple versions and even forks of images. Containers can be moved or copied to other computer systems or even organizations in order to reproduce a specific pipeline.

While it is easy to manage pipelines as a whole using snapshots, it can be quite complex for users to understand what is happening inside such a snapshot. For understanding the process, it is disadvantageous that the generation of the snapshot was done in an interactive way without enforcing to log all steps and programs that were involved. Essentially, a snapshot represents a black box with a behavior that can be reproduced very well but that can be complex to comprehend.

**Documentation management**

Documenting all pipeline steps and components leads to a description of the pipeline that makes it easier to understand its functionality. Placing the individual steps of a pipeline into a process description—for example using BPEL—can be achieved with reasonable effort. The situation with complex components or subsystems like R is more problematic. While it is possible to extract a list of all packages installed including the respective version, this list cannot be easily used for installing a new instance of R that exactly duplicates the first installation. Typically, only the latest versions available in the corresponding repositories of R and Bioconductor are used. For the installation of custom versions of R packages, individual installation procedures are required that go beyond documenting only package name and version.

For a fully automatic replication of a pipeline and its runtime environment, it is further necessary to use a documentation scheme that can be interpreted by a computer. Extensive testing of the document is necessary in order to ensure a complete
and error-free system. For each test, the whole pipeline environment has to be rebuilt from scratch. The whole pipeline development process has to be adapted to the documentation approach as a result.

**Hybrid approach**

We also analyzed a hybrid approach combining snapshotting and pipeline documentation for our tests based on the GEP-R pipeline. We implemented a Docker container only for the specific R environment in this case. The pipeline itself was managed and documented using the KNIME Server. The functional steps of the pipeline can easily be followed in the graphical notation with this approach. The black-box-effect of the Docker container is less significant since it is clear which specific functional step is called in the R environment.

**Discussion**

We assessed software tools and two different strategies for the documentation and archival of bioinformatics pipelines in order to facilitate reproducibility in our study. There are several factors that may influence the quality of bioinformatics pipelines: availability of a variety of tools for different steps, ability to handle changes in user requirements or tool versions. These factors can cause side effects such as small differences in results, but may have bigger impacts in terms of classifications and decision-making.

We considered three characteristics that are important for bioinformatics pipelines: stability, reproducibility, and ability to validate tools and versions. Changes in requirements and configurations may occur due to different reasons, such as frequent updates of tools, availability of new tools, and changes in requirements. A proper documentation strategy and version tracking allow smoother transitions and facilitate changes without disrupting the analytical steps or results.

We described two approaches for achieving these characteristics, each having its advantages and disadvantages. Snapshotting the whole pipeline is relatively easy to implement using virtualization technologies like Docker. However, it is not easy to follow the pipeline’s functionality. It is also not known for how long container runtime environment will be available. Documentation-based approaches provide pipelines that can easily be understood when looking at the whole process. However, they are more complex to implement. On the component level, they also face the problem that specific software components might not be available in the future.

A compromise of these two approaches is to document the high-level pipeline using tools like KNIME or BPEL. However, we suggest to use methods like Docker for individual components to conserve possible complex configurations for future use.

Research has been done to define formats for data expected to be used in future. More research is necessary to ensure the long-term availability of execution environments for the conserved pipelines.

**Conclusion**

Archiving raw data is considered good clinical practice as well as good research practice. However, in order for results derived from such data to be fully reproducible, it is necessary to archive biomedical analysis pipelines along with data as well as consider important requirements such as standardization and validation of all necessary software components.

Abstract

Diabetes and obesity are chronic diseases that need continuous follow-up. Analysis of the large volumes of patient data collected over time is time consuming and effortful for the physician. Automatic data abstraction and providing a summary of important events in the patient’s follow-up history saves the physician’s time and helps in making more informed decisions. The purpose of this study was to design an interpreter system that generates a tailored textual report about patients’ adherence to a therapeutic regimen. The system has been designed in three phases: determining report structure, interpreting data, and generating textual-graphical reports for the patient and physician. The output report was evaluated by 12 diabetes nutrition specialists and eight diabetic patients. We used a questionnaire and a semi-structured interview approach to assess the quality of the report in terms of content validity, understandability, and practicality.

Keywords:
Monitoring; Tailoring; Diabetes; Weight Loss

Introduction

As a chronic metabolic disease, diabetes cases are increasing nationally and globally. There is no definite cure for diabetes and it requires continuous lifelong care [1]. Studies have shown that 85% of diabetics are overweight [2]. It is commonly suggested that obesity contributes to the accelerated ischemic vascular disease and mortality of patients with type 2 diabetes [3]. It has been proven that weight loss improves survival in obese type 2 diabetic patients and improves life expectancy [4]. Centers for Disease Control and Prevention, states “The good news is that no matter what your weight loss goal is, even a modest weight loss, such as 5 to 10% of your total body weight, is likely to produce health benefits, such as improvements in blood pressure, blood cholesterol, and blood sugars” [5]. According to the World Health Organization (WHO), diabetes and obesity are preventable chronic diseases [6]. A main requirement of chronic disease management is continuous follow-up and adherence to therapeutic plans. In order to assess the patient’s compliance we need to monitor the degree to which a patient correctly follows medical advice. Since weight loss takes time and each doctor-patient visit requires recording several measurements, eventually recorded data increases in size, and subsequently its analysis becomes time consuming and arduous. Automatic data abstraction and providing it to the physician not only saves time and increases the physician’s awareness about the patient’s status, but also helps him/her to make informed decisions.

We have designed a system that interprets the patients’ condition in each phase of the treatment course according to guidelines as well as experts’ knowledge and experiences and have presented it as a textual report. Text generation is one of the key issues in NLP (Natural Language Processing) and follows either of two approaches: deep or shallow techniques. The former is based on semantic understanding and linguistic rules. The latter, however, uses simpler text generation methods that are domain-dependent [7]. Choice of the right approach depends on the purpose of the study. In shallow methods, there is a main template for the output text in which the pieces of data items are used to complete the statements based on the idiosyncratic characteristics and conditions of each patient. For each characteristic, a particular snippet has been incorporated within the system’s knowledge-base that is inserted in the right place in the text according to the defined criteria. In the present research, according to the formal structure and specified format of messages in medical sciences, the template-based method was used.

Most technology-based weight loss interventions are designed with the consumer-centric approach. A systematic review by Levine et al. shows that technology cannot replace human interaction, but serves as a complementary and facilitator tool to improve patient-physician communication [8]. One of the most important features of the proposed system is the possibility of generating two separate reports, one for physicians, and another for the patients. For the physician, the report provides an overview of the patient’s follow-up events and for the patient, the report consists of feedback and recommendations that are relevant to each patient. A body of research has indicated that personalizing medical advice in accordance with one’s needs, demands, and level of understanding would increase its efficacy [9].

In this paper, we have reported on a system designed by the authors that generates personalized reports for the diabetic patients’ adherence to weight loss recommendations. The method has been described, followed by the results of the analyses, and finally a discussion of the results and the probable causes and factors involved are presented.

Methods

System input is comprised of the data related to weight measurement and the related date along with the domain knowledge required to interpret it. System output is comprised of two separate written reports: one for the doctor and the other for the patient that is editable by the doctor. After the data analysis, the system gives an interpretation of the patient’s progress during the course of monitoring (Fig. 1).
The system has been designed in three phases: 1) specifying report structure, 2) rule-based data interpretation, and 3) generating textual/graphical reports for the patient and physician.

**Phase I: Specifying Report Structure**

The report addressed to the physician explores the patient’s condition from four aspects:

- Patient’s current status vs. expected status,
- Evaluation of the patient’s compliance throughout time (e.g. progress in loss of weight and the extent of following the treatment program),
- Estimation of the approximate time to reach ideal weight (prediction), and
- Providing useful information about the impact of weight loss on general health.

The first step in designing the weight monitoring system is the identification of data items based on the physician’s needs. These items were specified according to a review of literature [10] and interviews with domain experts and include: patient’s ideal weight based on his/her demographic and clinical features (such as age, blood glucose, prescribed medication and so on), BMI, length of monitoring, frequency of weight records, percentage of falling behind or exceeding the schedule, and the ideal time for achieving the desired weight.

The other report has been generated to address the patient and includes personalized feedbacks and recommendations.

**Phase II: Data analysis rules**

A rule-based approach was used to interpret the data. Two credible knowledge sources were used to extract rules concerning weight loss in diabetic patients: expert panel and the guidelines’ recommendations [10] [11]. Overall, 46 rules were found and represented as “if…then” statements in the system’s knowledge base. Figure 2 shows sample rules for the BMI interpretation.

If BMI>=16.5 AND BMI<18.5 Then
Inter = “UnderWeight”
ElseIf BMI>=18.5 AND BMI <25 Then
Inter = “Normal”

**Figure 2- BMI interpretation rules**

Rules are categorized in three groups based on their application:

- Rules concerned with patient’s adherence to follow-up, like the measurement intervals and the standard amount of weight loss per session.
- Rules associated with the weight loss program, estimating the ideal weight, patient’s status based on standard classification of obesity.
- Rules demonstrating the positive impacts of weight loss on diabetic patients’ health.

**Phase III: Report Generation**

The structure and components of the model obtained from the previous phase were implemented in the Visual Studio.net framework and Microsoft Access database. In this system, each patient has a unique identification code. There is a data entry form that makes a record of the measurements made in each visit. A sample report output is shown in Appendix 1. As can be observed, the data have been presented in different graphical formats like tables, diagrams, and texts. The structure of the report has two parts. The above section is used by the physician and presents the information about the extent to which the treatment course has progressed by the patient. The section at the bottom of the page is addressed to patients and aimed to make them aware of one’s progress. It was only availed to patients once confirmed by the physician. Figure 3 shows the text template that was completed with the appropriate patient’s data.

Results

One way of assessing the textual content of an automatic generated report is to compare it to a human-made report. However, human beings act mentally to write a textual report. Therefore, it is not possible to develop a gold standard to compare the system results. The evaluation methods of automatic reports are divided into two groups:

- Intrinsic evaluation: the generated report is assessed in terms of the internal quality such as cohesion and communication of information.
- Extrinsic evaluation: impact analysis of the generated report within the context of diabetes weight management.

We followed a two-phase approach to evaluate the generated report, considering perspectives from the patients and doctors. To this aim, we developed and validated a 6-item questionnaire based on [12]. Three representative sample reports was also generated by the system, to demonstrate the most prevalent patterns of the diabetic patients’ weight loss which consisted of irregular follow-up, follow-up as planned, and falling behind the program.

In the first phase, the sample report was submitted to 12 nutrition specialists and eight diabetic patients along with the 5-point Likert scale questionnaire, ranging from “Strongly Disagree” on one end to “Strongly Agree” on the other with “Neither Agree nor Disagree” in the middle. Table 1 shows the questionnaire with mean scores obtained by each group of physicians and patients, respectively. Values in the table are in percentage obtained through \(\text{mean scores} \times 100) / 5\). As the primary aim of our system is to assist physicians dealing with large volumes of data, we also compared the physicians' awareness about the patient’s visit/medical history in the current format and the generated report proposed in this study. To accomplish this, we made an information extraction template composed of essential data items needed for informed decision making, which was determined by physicians in a delphi study. The information extraction template consists of five data items including: patient’s compliance status to visit sessions, patient’s compliance status to the weight loss program, patient’s weight loss trend status, patient’s violation from ideal weight, and expected time to reach the ideal weight. We also determined a time limit for the physicians to fill out the template form. Physicians were first provided with the usual raw data of each visit session and asked to fill out the information extraction template within the pre-defined time limitation. They were then provided with the computer-generated report, and again asked to fill out the template form within the same time.

This assessment was done with 12 specialist for the three sample reports. The proportion of correct responses for each condition are shown in Table 2.

</table>

In the second phase, a semi-structured interview was conducted with both patients and doctors respectively and their opinions and perspectives regarding the quality and applicability of the report were assessed with open-ended questions. The doctors approved the usefulness of the content and agreed that it facilitated their decision-making. In this respect, they maintained: “Currently, to access the patient’s information, disperse information should be looked for in the patient’s records. It is both time-consuming and erroneous.” This report helps to avoid the foremost information in the shortest possible time to the experts. Another evaluator suggested sectionizing the content and highlight it in different colors in order to help find the intended information in shortest time. Participants also approved the adequacy of the content, but drew attention to the necessity of adding other factors related to weight loss such as the amount of calories intake, physical activity, percentage of fat and water in the body to practically apply the program in the doctor’s office. The experts found the patient’s report section as a useful and practical aspect. Here is a comment in this regard:

“The patient’s report is clearly elaborated and has a motivational effect. For more efficacy, reports can be sent to patients as a text message or email so that it prevents them from forgetting their treatment and encourages them to follow their treatment.”

Overall, the experts had a positive attitude towards using the system and the combination of text, tables, figures, and graphs to convey the results.

Discussion

Electronic interventions concerning weight loss such as text messaging, mobile, and web-based applications and other computer-based software have been primarily designed for patients’ self-monitoring. The output of these programs generally displays one’s progress in graphical diagrams and delegates the interpretation to the reader. This study is the first in its kind that provides an automatic explanation about patient’s status in text and graphic format both for the physician and patients.

Results show that the overall scores in the physician’s perspective were lower than patients in all six scales, which can be due to their more expertized view. The lowest score for both groups of audiences belongs to information adequacy, which indicates some information that the users were concerned about was neglected in the study. Comparing the current practice and the automatic generated report revealed that the physicians outperformed in working with structured, interpreted information rather than seeking patterns in mounds of raw, unstructured data.

Monitoring medical data is an essential task for clinicians in domains such as the ICU data stream [13] or diabetic patients’ blood glucose [14]. Numerous studies have documented the short-term benefits of weight reduction for patients with type II diabetes[15][16]. The weight loss monitoring report structure proposed in the present paper has been designed for use in a doctor’s office and helps the doctor to interpret the patient’s progress data precisely and in the least time.

Among the interpretive systems in medical sciences is PUFF II diabetes[15][16]. The weight loss monitoring report generation system, which has made them more popular in medical practice as compared to CDSS (Clinical Decision Support System), is that it does not give direct medical advice [18]. Instead, it provides a description of events and gives more emphasizes on important issues that reduces doctors’ resistance using them [19].

In the AI systems categorization, we can consider our system as a data-to-text generator. BabyTalk is a data-to-text summarizer system using natural language generation techniques to produce automatically nursing end-of-shift reports. It was developed in 2012 by Hunter et al. in the neonatal’s ICU of England’s Empire Clinic [13]. To evaluate this system, the nurses in the ward rated the textual report generating system in three dimensions: comprehensibility, accuracy, and usefulness. The results showed 90% comprehensibility, 70% accuracy, and 59% usefulness. The evaluation approach in the present research resembled the investigation just mentioned. However, the qualitative approach did not allow a comparison of the results.
Summarizing large volumes of data and interpreting it in an easy understandable fashion can be considered as the strong point of this study, which enables doctors to identify important patterns and trends in the shortest possible time, leading to enhanced patient safety, improved doctor-patient relationship, and improved physician decision-making.

Our system generates two different reports organized for the patient and the physician, which can be considered as a unique contribution not seen in previous studies.

Since the present research is a pilot study, the limited number of participants and the limited exposure time to the system are considered as the limitation of this research, which can affect the generalizability of the findings.

Our suggestion for future studies is to conduct a need assessment investigation to determine and addressed users' priorities and wishes prior to system development. Due to the importance of psychological issues in the care of diabetic patients, we suggest considering this aspect in future researches. We also suggest investigating the long-term effect of the system on the patients and physicians' performance.

Conclusions

The present research has shown that the quality of the report made by the system directly improved the physician's performance and can potentially contribute to better medical outcomes. The criterion for evaluating the present system has been the qualitative content analysis of the report. The majority of the existing weight loss programs measure weight lost as an index of the efficiency of the intervention.

The results have suggested that automatic data abstraction is required by specialists in different healthcare domains, provides more information to the physician, and saves time for better patient-physician communication. It is recommended that researchers further investigate other relevant factors adding up to the generated report such as weight management, the amount of calories intake and physical activities. How each factor changes through time and how the other factors are correlated need to be investigated as well. The present findings have shown that the cooperation of healthcare specialists and IT researchers can lead to the design of practical systems that are warmly received by the medical staff. The present researchers believe that the proposed model can be applied in all monitoring programs of patients with chronic diseases as is required in the healthcare world today.

Acknowledgements

This study is the first author’s PhD dissertation, which has been supported by a grant [Grant # 950392] from the Mashhad University of Medical Sciences Research Council. The authors would like to acknowledge the diabetes specialists from the Endocrine Research Center for their participation in the evaluation of the interviews.

Appendix 1: A report sample

**WEIGHT LOSS REPORT**

**Patient’s code: 10**

**Date: 12/19/2016**

<table>
<thead>
<tr>
<th>Patient’s name: Ali Ahmadi</th>
<th>Age: 36 yrs</th>
<th>Type of weight loss program: Normal</th>
<th>Beginning Date: 12/19/2016</th>
</tr>
</thead>
</table>

**Doctor’s report:**
Ali Ahmadi’s ideal weight is 74 kilograms. So, right now, he has 28 kilograms of extra weight. His BMI is 33 and belongs to class 1.
The frequency of recording his weight has been 11 since 18 months ago which shows a moderate rate of follow-up. Moreover, in 60% of cases, the measurement intervals have been delayed which show his moderate rate of follow-up. Considering the standardized loss of 1.5 kilogram a week, ideally speaking, we expected a 27-kilogram loss since the outset. As compared to the 8 kilograms lost so far, there shows to be a 70% of falling behind the program. Ideally, one is expected to reach the optimal weight within the forthcoming 19 weeks. However, due to the current trend, this can be expected to happen in 29 weeks.
The weight loss rate has been estimated in all cases to be below the threshold level which indicates that the patient fell behind the plan.

**Patient’s Report:**
You have managed to reduce 30% of the amount you are overweight according to the time spent from the starting point, this value should be around 90%. By following this process it takes seven and a half months to reach the ideal weight. While if you do more regular weight measurements and follow the prescribed diet and weight loss it reduce to four and a half months. Here you have a weight loss of 8 kg, significantly reduced the risk of heart disease and have added at least 2 years to your life expectancy.

Physician’s Name .......
An Infrared Thermal Images Database and a New Technique for Thyroid Nodules Analysis

José R González, Charbel Damião, Aura Conci

*Computing Institute, Federal Fluminense University, Niterói, Rio de Janeiro, Brazil,
Antonio Pedro University Hospital, Federal Fluminense University, Niterói, Rio de Janeiro, Brazil

Abstract

Thyroid nodules diseases are a common health problem and thyroidal cancer is becoming increasingly prevalent. They appear in the neck and bottom neck region, superficially over the trachea. Cancer tissues are characterized by higher temperatures than surrounding tissues. Thermography is a diagnostic tool increasingly used to detect cancer and abnormalities. Artificial intelligence is an approach which can be applied to thyroid nodules classification, but is necessary to have a proper number of cases with proven diagnosis. In this paper, a new database that contain infrared thermal images, clinical and physiological data is presented. The description of each nodule per patient, and the acquisition protocol (based on Dynamic Infrared Thermography approach) is considered as well. A semi-automatic method for image registration was implemented to pre-process the thermograms and a new method for the Region of Interest (ROI) extraction is proposed. Moreover, the obtained ROI results are confirmed by medical specialists and turned available for future comparison with other works.

Keywords:
Thyroid Nodule; Infrared Rays, Diagnosis; Thermography

Introduction

The thyroid is an endocrine gland located at the human neck, next to the thyroid cartilage and over the trachea. Thyroid nodules are a common clinical problem and differentiated thyroid cancer is becoming increasingly prevalent. Epidemiologic studies have shown the prevalence of palpable thyroid nodules to be approximately 5% in women and 1% in men living in iodine-sufficient parts of the world. In contrast, high-resolution ultrasound (US) can detect thyroid nodules in 19%–68% of randomly selected individuals, with higher frequencies in women and the elderly [1]. The clinical importance of thyroid nodules investigation is for exclusion of thyroid cancer, which is prevalent in 7 to 15% of cases, depending of factors as age, sex, exposition to radiation, and familiar history [2].

The temperature distribution on the human skin can be measured by using infrared cameras and stored in a thermal image. These images represent a temperature pattern of the body, which is highly symmetric around the vertical axis of the sagittal plane. Variations of this symmetry in a serial imaging can constitute a sign of abnormality. Thermal imaging is an inexpensive and non-invasive technology that has been applied in many fields, including sport medicine, forensic medicine, anesthesiology, peripheral vascular diseases, and cancer and breast diseases diagnosis [3]. Heat pattern measurement by thermography, is fast, non-contact and non-invasive [4].

A malignant tumor is related to abnormal growth of cells, invading tissues and spreading to other regions of the body. These tumors need nutrients to grow and lead to the development of new blood vessels around them (angiogenesis) [5;6]. Due to increased blood flow, tumors frequently present higher temperature than the surrounding region, which can be acquired by thermography and used to aid in the diagnosis of malignant thyroid tumors [7]. In addition, toxic autonomous nodules tend to be large (>2.5 cm) and this may be increase the possibility of detection [10].

Thermography detects physiologic or functional changes on the surface of the skin and the Penne’s equation [8] or artificial intelligent methods can be used for detect the possible internal cause of such thermal pattern. Thermograms are sensitive to environmental changes in temperature, humidity and air circulation. Moreover, they should follow the same acquisition protocol to standardize the process and minimize the intra and inter patient thermograms variations. Additionally, the thermograms must be preprocessed in a proper way to minimize possible errors. Discriminated features need be extracted for neck region (Regions of Interest, ROI) and used as input in algorithms for pattern recognition. This work proposes a protocol for infrared image acquisition; a database for thyroid study with infrared images and clinical data and a method for ROI autonomous identification and image registration of thyroid region.

Background

The thyroid nodule diagnosis using thermography has been studied in few works in the literature. A numerical analysis of the area by Finite Element Method is proposed by Helmy et al. [3, 9]. The authors also compare numerical simulation with a thermal image of the thyroid gland for the same patients [10]. Gavriloaia et al. [11;12] explain details of a system for infrared image acquisition to study thyroid nodules and analyze them by Penne’s equation. However, few infrared images are explored to find infrared signatures that can be used as descriptors of the thyroid tumors [11]. They use the ABCDE investigation method (based on Asymmetry, Border, Color, Diameter and Evolution of the contour) and affirm that their method can correctly identify 89.3% of the investigated patients with thyroid cancer. Moreover, they apply fractal analysis to quantify the irregularity in size and shape of thermal signatures of tumors and use self-similarity and lacunarity features [13].

Same authors purpose an improved method for IR image filtering [14] as well. This study is aimed at developing a numerical scheme which significantly reduces the computer time for thermal image denoising with edge preservation. This filter allows physicians to assess faster than using other anisotropic diffusion filters, the contour shape, to locate the outbreaks in ROIs. Other filtering types are used for improve the thermals images and for Empirical Mode Decomposition [15].

The results of thermography of thyroid dysfunctions are presented as an alternative clinical diagnostic technique...
Finally, the thyroid images are classified as hypothyroid, hyperthyroid (defined as the differences between the pixel pairs maximum in the block, Normalized Multi-Scale Intensity Variation, difference between the number of pixels in a block filtered by using median filter, and enhanced by histogram equalization. Segmentation of the images and ROI extraction are done by using modified Otsu Technique. Texture features were extracted by using Gabor’s filters and wavelet. Contrast, Homogeneity, Entropy and Energy features from the gray level co-occurrence matrix are used as well. Classification is done by a Multilayer Perceptron Network (MLPN).

Other system to detect the thyroid gland disease using thermography is proposed \cite{18,19}, where the patients’ neck are captured by using a FLIR-E30 camera. These images were filtered by using median filter, and enhanced by histogram equalization. The segmentation of the images is done using Otsu's Technique, features are then extracted from region of interest: mean, variance of the low-low-frequency sub-band Otsu’s Technique, feature are then extracted from region of interest is segmented. Globals and locals features are used as well. Classification is done by a Multilayer Perceptron Network (MLPN).

Methods

Recent applications of thermography in medicine showed the effectiveness of Dynamic Infrared Thermography (DIT) in medical research. The DIT is a method for monitoring the dynamic response of the skin temperature after thermal stress in a period of time \cite{20}.

DIT Protocol for thyroid thermograms

We recommended that at least thirty minutes before the examination, the patient should avoid: alcohol, caffeine, physical exercise, nicotine, and should not apply any cream, oil or chemical substance to the neck region. Initially, the patient was asked to sit still in order to minimize the possible displacements; the distance from the camera to the patient was 0.5 to 0.6 meters. The relative humidity of air and room temperature were recorded and inserted as parameters in the camera. Room temperature was maintained between 22 °C and 25 °C, no doors and windows openings and with only fluorescent bulbs. Patients were requested to remove earrings, necklaces or any other accessory that can be seen in the thermal image and use a hair band. Body temperature was checked using a thermometer. Patients were seen in the room twenty minutes before starting the examination and were seated with their head tilted slightly back and looking up while capturing images. An air flow (electric fan) was directed to the patient, when the mean temperature of the skin decreases to 29 °C, and this ventilation was stopped and the sequential acquisition was started. The cooling of the neck region improved the thermal contrast between healthy and unhealthy tissues. One image was captured every 15 seconds over five minutes, producing one sequence of twenty images.

Database

The database presents data and images from volunteers and patients of Federal Fluminense University Hospital (named Antonio Pedro University Hospital – HUAP – www.uff.br/huap/) in Niteroi, Rio de Janeiro, Brazil. In this work, we use data from 25 volunteers (twenty with benign thyroid nodules, and 5 healthy as control group). The average age was 54 and female was the predominant gender. A FLIR thermal camera model SC620 was used to capture the thermograms. The sensitivity of the camera was smaller than 0.04°C and images had a dimension of 640x480 pixels. The image acquisition and their use for research was approved by the Ethical Committee of the HUAP and registered at the Brazilian Ministry of Health under number CAAE: 57078516.8.0000.5243. The database is accessible at http://visual.ic.uff.br/thyroid/.

Processing methods for patients classification

The proposed methodology for this is divided into four stages. First, the thermograms are registered to minimize the thermograms acquisition errors. Then, a neck and sub-neck region where thyroid nodules are located is segmented (the region of interest is segmented). Globals and locals features from ROI of each image are extracted to create few time series by patient. In the last stage, decision is performed by pattern classification of time series.

Image Registration

The protocol for image capture was designed to standardize the process and minimize the errors that can occur during the thermograms capture process, but movements of patients can occur, causing misalignments between the images (Figure 1), and error in further processing.

Two general types of movement can be identified: i) full-body modification, that include lateral movements to the left or right, to the top or bottom, or combinations of both; and ii) local modifications, that include movements related to perspective and distortion, such as tilts of the head to the back or front.

We use rigid transformation (translation and rotation) to correct the full-body modification. The first image is considered as reference or source, and each one of others as destination. At least two correspondent points are required to determine the rigid transformation $T$ (Equation 1) that maps the coordinates of the pixels $x = (x_1, x_2, 1)$ of source image into a new coordinates $x' = (x'_1, x'_2, 1)$ of sensible image, where $x' = T \cdot x$. \n
![Figure 1 - Movements of a patient during the thermograms acquisition.](image)

a) b)
After the registration process we extract the region of interest to focus the analysis in the neck region (thyroids). The ROI of the reference image (the first) is extracted using the algorithm proposed in this section. ROI is then identified for each of the other registered images.

The automatic algorithm proposed to ROI extraction is based on locating the neck region and the bottom neck area. The neck region is assumed be in the narrowest part of the patient body. The pre-processing step of thermograms is very important to collect under the proposed protocol.

A database was created for thyroid nodules research. This contains 25 cases with proven diagnosis. All cases were collected under the proposed protocol.

Conclusions

This work performs an overall analysis of thermography images, focusing on thyroid infrared image acquisition, processing and analysis, with is a new field of study. We analyze data critically in order to extract relevant information that can help in artificial intelligence conclusion related to cancer diagnosis by using such images.

A new database was created and published for researches on thyroid nodules diagnosis. We proposed an autonomous ROI identification method, which is based on very simple fundamentals of computer vision. As continuation of this work we will consider: (1) developing a automatic algorithm for selecting reference points (based on anatomical identification of the patients’ neck to been used as correspondent points in image transformations in the registration process); (2) analyzing non-rigid methods for the image registration process; (3) include others features to be used in the classification and (4) promoting a classification step by using data mining algorithm.

Automatically Identifying Topics of Consumer Health Questions in Chinese

Haihong Guo, Xu Na, Jiao Li

Institute of Medical Information & Library, Chinese Academy of Medical Sciences, Beijing, China

Abstract

In health question answering (QA) system development, question topic identification is crucial to understand users’ information needs and further facilitate answer extraction. This paper presented a machine-learning method to automatically identify topics of health related questions in Chinese asked by the general public. We collected 2000 questions from Chinese consumer health websites, and characterized them using 17 types of features such as lexical, grammatical, statistical, and semantic features. This method was applied to identify 6 health question topics of Condition Management, Healthy Lifestyle, Diagnosis, Health Provider Choosing, Treatment, and Epidemiology. The results showed that the average F1-scores of the above 6 topic identification were 99.63%, 99.13%, 98.55%, 96.35%, 76.02%, and 71.77%, respectively.

Keywords:
Information Storage and Retrieval; Machine Learning; Medical Informatics.

Introduction

Generally speaking, a question answering (QA) system is composed of three key modules: question analysis, information retrieval, and answer extraction. Nowadays, QA systems widely used the natural language processing (NLP) techniques from question identification to answer generation [1]. As the first step, question classification plays a critical role in identifying users’ information needs from the various and free expressions using natural language. Correct question classification would limit the retrieval scope and improve answer accuracy [2].

Automatic question classification methods are divided into rule-based and machine-learning based ones. Rule-based methods use the question format and domain knowledge as classification rules, which work well for classifying “5WH” (i.e. what, where, when, who, why, how) questions but failed to solve complicated ones [2-3]. The machine-learning based methods are effective in learning classification rules from large-scale real corpus and delivering more objective and reliable results. The features of machine-learning based question classification include the following 5 categories [2,4]: a. lexical features such as bag-of-words (BOW) and part-of-speech (POS); b. grammatical features such as interrogative words (IW), noun/verb phrases and their grammatical functions; c. semantic features such as controlled terminologies and their semantic types (ST); d. pragmatic features such as emotional words and context scenarios; e. statistical features such as question length (QL), word length (WL), and term frequency-inverse document frequency (TF-IDF) etc. The widely used algorithms include support vector machines (SVMs), naive bayesian, decision tree, maximum entropy, logistic regression, and conditional random fields.

Several studies have been conducted for question classification in health and medical field in English, such as identifying general topics of clinical questions [5], distinguishing answerable and unanswerable intensive care unit (ICU) questions [6]; separating consumer health questions from professional medical questions [7], and classifying question types for consumer health questions [8]. Chinese question processing has its challenges in word segmentation, feature representation and selection, and classification algorithm improvement[3]. Some efforts have been made towards the general Chinese question classification, for instance, developing a question property kernel function which combines syntactic dependency relationship and POS [9], designing an alternating and iterative One-against-One algorithm [10], and developing a semi-supervised method with jointly learning question and answer representations [11]. It is worth noting that questions of health and medicine have their own characters such as circumscribed content, unique terminologies, and complex expression [12]. Few works have been investigated on Chinese consumer health question classification.

In this study, we designed a machine-learning method to automatically identify topics of consumer health questions in Chinese.

Materials and Methods

Data Set

A total of 2000 questions were manually annotated with one or more categories by the classification schema of consumer health question built in [13], and these questions were randomly selected from nearly 100 thousand hypertension-related messages posted by consumers on a Chinese health website (xywy.com). The distribution of questions on the primary level categories is shown in Table 1.

Feature Selection

We explored various features for machine-learning, including lexical, grammatical, semantic, and statistical information obtained from the initial BOW.
This study aimed to select the most discriminative features from the enormous amount of dimensions of feature space, then the positive and negative instances are given training vectors whole, positive, and negative data sets respectively; defined as following [20].

- BOW: Word segmentation was executed by Rwordseg [14], a Chinese word segmentation tool under R environment based on the Institute of Computing Technology, Chinese Lexical Analysis System (ICTCLAS), which reached a precision of 97.58% on the 973 experts testing [15].
- POS: The Chinese POS tagging was executed by the Stanford Parser (Version 3.3.1) [16].
- IW, noun head chunks (NHC), verb head chunks (VHC), noun rear chunks (NRC), verb rear chunks (VRC), IW + NHC/VHC, and NRC/VRC + IW: A dictionary of 42 Chinese interrogative words was developed manually based on baike.baidu [17] and general types of Chinese consumer questions that summarized by our former research [13]. NHC/VHC represents the first noun/verb after IW in a question. While NRC/VRC represents the last noun/verb before IW. They are likely to be the dependent word of the IW that help to express the semantic information of the question [18].
- Chinese Medical Subject Headings (CMeSH) concepts and ST: Medical concepts in the question and their ST were recognized by using the controlled vocabulary of CMeSH [19]. Three ST were considered: Disease, Drug, and Symptom.
- Keywords: Three ways to extract the keywords of a question were explored in this study: a. taking the first k words with maximum TF; b. taking the first k words with maximum IDF; c. taking the first k words with maximum TF-IDF. The heuristic equation (1) developed by Cao YG et al [5] was adopted to calculate k, which was based on their observation that the number of keywords increases when the question length increases.

\[ k_{qi} = \begin{cases} \frac{n_{qi}}{6} + 1 & \text{if } n_{qi} > 12 \\ 3 & \text{otherwise} \end{cases} \]

Where \( k_{qi} \) is the number of keywords extracted from the \( l \)-th question, and \( n_{qi} \) is the number of words in the \( l \)-th question.

- Statistical features: including QL, max WL, min WL, average WL, max TF, min TF, average TF, max IDF, min IDF, average IDF, max TF-IDF, min TF-IDF, and average TF-IDF. The corpus used to calculate the IDF of each word contained nearly 100 thousand hypertension-related messages collected by our former research [13].

This study aimed to select the most discriminative features from the enormous amount of dimensions of feature space, some of which may either do nothing or degrade the performance of the classifiers. \( \Phi \)-score that measures the discrimination of two sets of real numbers is a convenient technique used to achieve effective feature selection, which is defined as following [20].

Given training vectors \( x_{s,t}, s = 1, ..., m \), if the number of positive and negative instances are \( n^+ \) and \( n^- \) respectively, then the \( \Phi \)-score of the \( p \)-th feature is defined as equation (2).

\[
\Phi_p(x) = \frac{(x_{s,t}^{(+)} - x_{s,t}^{(-)})^2 + (x_{s,t}^{(-)} - x_{s,t}^{(+)} - x_{s,t}^{(0)})^2}{1 + x_{s,t}^{(+)} - x_{s,t}^{(-)} - x_{s,t}^{(0)}} \]

Where \( x_{s,t}^{(+)} \), \( x_{s,t}^{(0)} \), \( x_{s,t}^{(-)} \) are the average of the \( p \)-th feature of the whole, positive, and negative data sets respectively; \( x_{s,t}^{(0)} \) is the \( p \)-th feature of the \( s \)-th positive instance, and \( x_{s,t}^{(-)} \) is the \( p \)-th feature of the \( s \)-th negative instance. Numerator in the equation indicates the discrimination between the positive and negative sets, meanwhile, denominator indicates the one within each of the two sets. The larger the \( \Phi(t) \) is, the more likely this feature is more discriminative. Therefore, we used \( \Phi(t) \) as the feature selection criterion, and the implementation steps were as following:

1. Calculate \( \Phi(t) \) for each feature;
2. Calculate the \( \hat{\Phi} \) (average \( \Phi \)) of each type of features, and further set it as the threshold of the corresponding feature type. We choose \( \Phi \) as the feature selection threshold because the distribution of \( \Phi \) differ greatly between different types of features (Table 2), while this method can help to keep all the useful features in different types [21].
3. For each type of machine-learning features, select features with \( \Phi \geq \hat{\Phi} \) within their affiliated type.

**Classifiers**

Since the questions were multi-labelled, the task in this paper was a multi-label classification problem, which was usually transformed into one or more single-label classification or regression problems [22]. We therefore transformed the task into six binary classification problems (one-versus-rest for each) so as to suit the SVMs [23], which was commonly used and claimed to be the best in related works [5-8]. We used machine-learning algorithms within the R project for statistical computing (version 3.3.1) [24] for automatic question classification, including SVMs, naive bayesian, decision tree, maximum entropy, logistic regression, and conditional random fields.

**Training and Testing**

As shown in Table 1, the distribution of consumer questions to different topics is skewed, with a large majority of questions assigned to the topic of Treatment (1167, 58.35%), and Diagnosis (600, 30%), while only 45 (2.25%) questions were assigned to the topic of Health Provider Choosing. To compare the performance of different binary classifiers, this study applied the under-sampling method for the majority class, which could ensure each classifier was trained and tested on the same number of “positive” and “negative” questions. For example, when we trained a binary classifier for Diagnosis, there were 600 questions as positive cases (Table 1), then we have to select 600 negative cases randomly from the total amount of 1400 negative cases to keep the balance. Therefore, the sample data was composed of two distinct cases: the positive and the negative.

We then split the sample data for each binary classifier into two sets, 30% for independent test, 70% for 10-fold cross-validation, in which the sample data was equally divided into 10-folds, one of them was used as testing data, meanwhile, the remaining 9 folds as training data. The cross-validation process was repeated 10 times (equal to the folds) and the average value and standard deviation was reported. The advantage of this method was that all cases in the sample data was used for both training and validation, and each case was used for validation exactly once [25].

**Evaluation Metrics**

The performance were measured by precision (P), recall (R) and F1-score (\( F_1 = \frac{2 \times P \times R}{P + R} \)), which were commonly used in text retrieval tasks.
Results

Machine-Learning Features Selection

We calculated the \( \Phi \)-score of every feature for each binary classification, and found that their distribution between different types of features differed greatly. The performance of features with \( \Phi \geq \bar{\Phi} \) was not less than that of all the features in the corresponding types, and some of them even higher than the latter. For example, the topic of Diagnosis (Table 2), the \( \bar{\Phi} \) of bag-of-words was 0.0009 with a standard deviation of 0.0029, while the value of IW was 0.0021 and 0.0079 respectively. When taken all the 6154 features in POS as input features, the average \( F_1 \)-score was 73.92%, while just took the 2140 features with \( \Phi \geq \bar{\Phi} \), the performance increased to 79.49%. Similar cases can be seen in feature types of IW, and keywords with maximum TF, IDF and TF-IDF respectively, etc. Which interestingly indicated that some of the features in each type either do nothing to the classifiers or have some side effects on it. It’s quite important to reject these features because it could not only save the computing resources so as to increase the efficiency, but also improve the performance of the classifiers. Therefore, we set \( \bar{\Phi} \) of each feature type as its feature filtering threshold, and selected the features with \( \Phi \geq \bar{\Phi} \) as input machine-learning features, so as to keep all the useful features in different types and improve the performance of the classifiers. Thus, each classifier received a different feature set, and the number of features within them were shown in the third column in Table 4. For example, the MaxTF was an effective feature for the classifiers for Treatment, Condition Management, Provider choosing, and Lifestyle, but not for the classifier for Diagnosis.

Note: For each type of features, \( \bar{\Phi} \) is the average \( \Phi \), \( \sigma(\Phi) \) is the standard deviation of \( \Phi \), \( n_{\Delta F} \) is the total number of features, \( n_{(\Phi \geq \bar{\Phi})} \) is the number of features with \( \Phi \geq \bar{\Phi} \), \( F_{1_{\Delta F}} \) is the average \( F_1 \)-score of the classifier using all the features within this type, and \( F_{1_{(\Phi \geq \bar{\Phi})}} \) is average \( F_1 \)-score of the classifier using only the features with \( \Phi \geq \bar{\Phi} \) within this type.

Performance of General Topics Classification

The single reported result in this study was from SVMs in the kernlab package which worked best from all different classification algorithms available in the R project for statistical computing. The performance of topics classification of each classifier with all the 15,349 features in each feature type as shown in Table 3, and the performance with features which \( \Phi \geq \bar{\Phi} \) of each feature type was shown in Table 4. The research findings showed that by dropping features under the threshold, we could not only removed 65.40% to 85.13% of the features, but also improved the performance of each classifier. For example, the average \( F_1 \)-score of the classifier for Diagnosis dramatically increased from 79.84% to 98.55%. The results of 10-fold cross validation on each binary classifier affirmed the hypothesis we proposed in the former section.

As shown in Table 4 and Table 5, we reached excellent performances on the classification of most topics of consumer health questions in Chinese, including Diagnosis, Condition Management, Healthy Lifestyle, and Health Provider Choosing, with all the evaluation metrics (average precision, recall and \( F_1 \)-score) above 90%. We reached moderate performances on the classification of Treatment and Epidemiology, with most of the evaluation metrics between 70% and 80%. The standard deviation of each evaluation metric indicated that the performance of each binary classifier was relatively robust.

Discussion

Comparison with Related Works

This study explored the possibility of using classifiers to identify topics of Chinese consumer health questions automatically and the feature selection by machine-learning to improve the efficiency and performance of each classifier. Compared to other related studies on question classification (Table 6), there were three specialties in this study. Firstly, Chinese consumer health questions were chosen as the research object. Secondly, some feature types explored were more abundant than others. Our work adopted almost all the effective features in the prior works with the UMLS concepts and ST replaced by CMeSH concepts and ST. We also explored three ways to extract the keywords of a question as the machine-learning features, i.e. took the first k words with maximum TF/IDF/TF-IDF as keywords. In addition, we added NRC/VRC + IW according to the specialties of the word order in Chinese language. For example, in the question of “My grandpa is more than sixty years old and have hypertension, what way can make him better?”. The IW is what, the NHC is way, and the NRC is hypertension. While the question “My grandpa is 73 years old, his blood pressure is 90-160, is it hypertension?” has the IW in the last location of the sentence, so it has no NHC, but has a NRC.

Lastly, the feature selection methods in our work were quite different from other related works. Cao Y [5], Patrick J [6], Liu F [7], and Roberts K et al [8] employed a method of combining different types of features without considering the threshold, in which they explored different combinations of different feature types and selected the best combination with maximum F1-score of the classifier. Thus, a feature type would be either picked up or rejected, which may cause the loss of some effective features in the rejected types. Another disadvantage was the difficulty in exploring all the possible combination of different feature types. Taking a task with 10 types of features for example, it would need to explore 1023 (equal to 2^10 - 1) combinations [27], which was time and resource-consuming. The limited combinations explored in their methods could severely affect the improvement of the classifiers’ performance. On the contrary, this research adopted a much more efficient method to combine all the discriminative features from each feature type with \( \Phi \geq \Phi \).
which was also proved to be very effective (as described in the Results section).

Since the methods proposed in this paper and those in the related works were experimented on different datasets in different languages, it might be ineffect to compare the effectiveness of these methods, although the performances of the classifiers trained by our study were quite satisfying.

Limitations

One of the limitations of this study was that the corpus we used to train the classifiers was come from only one Chinese health website, which was focused on hypertension related questions. Therefore, the validity of these classifiers for the vast majority of questions from other websites and other diseases remained to be tested. Another limitation of this work is that we only reached moderate performances on the classifiers for the topics of Treatment and Epidemiology. Whereas the error analysis was missed due to the space limitations of this paper.

Conclusion

This study presented a method to automatically identify the topics of consumer health questions in Chinese, so as to facilitate users’ information needs extraction and answer retrieval. We explored an abundant feature types and adopted a novel method to select all the effective features with $\Phi \geq \tilde{\Phi}$. The performance of the classifiers trained was quite satisfying.

Detecting Protected Health Information in Heterogeneous Clinical Notes

Abstract

To enable secondary use of healthcare data in a privacy-preserving manner, there is a need for methods capable of automatically identifying protected health information (PHI) in clinical text. To that end, learning predictive models from labeled examples has emerged as a promising alternative to rule-based systems. However, little is known about differences with respect to PHI prevalence in different types of clinical notes and how potential domain differences may affect the performance of predictive models trained on one particular type of note and applied to another. In this study, we analyze the performance of a predictive model trained on an existing PHI corpus of Swedish clinical notes and applied to a variety of clinical notes: written (i) in different clinical specialties, (ii) under different headings, and (iii) by persons in different professions. The results indicate that domain adaption is needed for effective detection of PHI in heterogeneous clinical notes.

Natural Language Processing, Electronic Health Records, Data Anonymization

Introduction

Healthcare documentation has effectively been digitized as a result of the widespread adoption of electronic health record (EHR) systems. This has, in turn, enabled enormous amounts of valuable data — describing health conditions, treatments and their effects over time — to be analyzed by means of computational methods. To that end, research on developing methods for large-scale analysis of EHR data has surged in recent years, with the promise of improving the effectiveness and efficiency of healthcare, as well as supporting medical research and epidemiological activities [1,2]. However, in order to facilitate the secondary use of EHR data, there is a need for privacy-preserving measures, in particular ones capable of obscuring the sensitive information that is often prevalent in free-text clinical notes. In the absence of informed consent, de-identification is indeed a prerequisite for the secondary use of EHR data: in the U.S., the Health Insurance Portability and Accountability Act (HIPAA) defines 18 types of protected health information (PHI) that should be obscured for EHR data to be considered de-identified [3].

Approaches to automatic de-identification of clinical text can be categorized broadly into rule-based methods and those that employ machine learning [4]. Rule-based methods rely on heuristic rules defined by domain experts, often in conjunction with dictionaries. While rule-based systems sometimes perform well, they are often cumbersome to develop and tend to generalize poorly to new datasets. The machine learning approach is typically supervised, which means that the learning algorithm relies on manually labeled examples — in this case of PHI — for constructing a predictive model. There are pros and cons of each approach: rule-based systems tend to perform better on rare PHI, while machine learning systems are better able to identify PHI types that are not covered by the employed dictionaries [4]. In the 2006 i2b2 de-identification challenge, machine learning systems performed best [5]. In recent years, the predictive performance of these methods has been improved by, for instance, enriching the feature space describing the data with word embeddings [6,7] or employing alternative learning algorithms, such as deep neural networks [8].

A bottleneck of supervised machine learning is the need for access to labeled examples. In order for predictive models to learn to identify rare classes, in particular, large amounts of data often need to be annotated by domain experts. In the healthcare domain, such resources are scarce and particularly expensive to create. The problem is further exacerbated by the need to cater not only to a multitude of human languages, but also to various sub-domains: performance tends drops when a predictive model is applied to out-of-domain data, i.e. when the target data is sampled from a different distribution than the training data. In EHRs, there are potentially large domain differences that may need to be accounted for when leveraging predictive modeling to, for instance, automatically identify PHI in clinical text. There are domain differences with respect to various clinical specialties and types of notes, which have been found to be reflected in the vocabulary and linguistic structure of the narrative documentation [9,10]. Different types of clinical notes, moreover, adhere to various levels of formality: discharge notes, for instance, tend to be more formal and function as letters to the general practitioner and other caregivers, while, for example, daily notes are less formal in nature and are primarily intended for the caregiving team, describing health status and progress, and are sometimes also used as memory notes in the ongoing healthcare process. There are also likely to be differences with respect to the author of a clinical note, not only in terms of individual styles and idiosyncrasies but depending on the author’s profession, for instance whether it is written by a physician or a nurse. The fact that the content, tone and function of clinical notes often differ substantially may have an impact on the prevalence and expression of PHI, about which very little is known. In a recent study, however, we observed distinct differences in PHI density in clinical notes written by practitioners in different professions, in different specialties, and under different headings [11]. The aim of this study is to investigate whether domain differences in health records may influence the ability of a predictive model, trained on a mixed corpus, to detect PHI in heterogeneous clinical notes.
Methods

In this study, a pre-existing PHI corpus is used for training a predictive model that is subsequently evaluated in nine sub-corpora corresponding to different types of clinical notes. We investigate the prevalence and distribution of PHI in the nine sub-corpora, comprising manual annotations of PHI, and evaluate the ability of the predictive model to detect PHI in the potentially heterogeneous clinical notes. The clinical notes, both in the pre-existing PHI corpus and the newly annotated sub-corpora, are part of the Stockholm EPR Corpus\(^1\), which contains health records in Swedish from Karolinska University Hospital. Names and other sensitive information has been removed from the structured data fields; however, PHI is present in the free-text clinical notes, which may include personal data about the patient, family members, as well as other caregivers in the healthcare process.

The pre-existing PHI corpus comprises 100 health records, in the form of clinical notes, produced in five clinics in 2008: Neurology, Orthopaedics, Infection, Dental Surgery and Nutrition. The clinical notes were manually annotated by three annotators for a set of 28 PHI classes based on HIPAA definitions and enriched with additional, more fine-grained classes — see [12] for more details on the corpus creation process. A consensus-based gold standard was later derived from the original annotations after discussions between the annotators [13]. This process included merging conceptually similar classes, resulting in the following eight classes: First Name, Last Name, Age, Health Care Unit, Location, Full Date, Date Part and Phone Number. The version of the corpus used in this study contains a total of 198,466 tokens and 4,220 annotated PHI instances. The PHI density — calculated as the number of PHI instances divided by the total number of tokens — is 2.13% and the class distribution is as follows: Health Care Unit (23.9%), First Name (21.7%), Last Name (21.5%), Date Part (16.6%), Full Date (8.7%), Location (3.3%), Phone Number (3.2%), Age (1.2%).

This latter version of the corpus is then used for training a predictive model. To that end, a linear-chain conditional random fields (CRF) [14] is used that, in addition to being predictive model. To that end, a linear-chain conditional random fields (CRF) [14] is used that, in addition to being

\(^1\) This research has been approved by the Regional Ethical Review Board in Stockholm (2012/834-31/5).

A tuned CRF model is then applied on data extracted from 2009 in order to evaluate the predictive performance on different types of clinical notes. All clinical notes produced in 2009 — i.e., a different year in order to avoid any overlap with the training data and potential bias in the obtained performance estimates — are considered and grouped into three categories according to three dimensions, resulting in a total of nine sub-corpora:

a) **Speciality** — clinical notes produced in different types of clinics: Geriatrics, Oncology and Orthopaedics (including surgery)

b) **Heading** — clinical notes written under different headings: Admission, Day, Discharge. Various headings belonging to these general categories are grouped together.

c) **Profession** — clinical notes written by clinicians in different professional roles: Physician, Nurse, Physiotherapist.

It should be noted that when categorizing notes within one particular dimension, the other dimensions are ignored, which means that a note may exist in more than one sub-corporus, but not across sub-corpora in the same dimension. In order to enable evaluation of predictive performance, subsets of the data are manually annotated. From each sub-corporus, 750 sentences are randomly sampled and annotated by a senior physician using the BRAT annotation tool [17]. The definitions of the eight PHI classes used for the annotation of the corpus that is here used for training the CRF model [12,13] are adhered to; however, elaborate annotation guidelines are not available. For the manual annotation in this study, a number of rules-of-thumb are followed, such as selecting the largest possible scope describing a PHI and not permitting nested or split annotations. Full Date is moreover defined to contain year, month and day, while Date Part does not comprise all three elements. Age is annotated together with information indicating its status as an age and not just a number, e.g. “A [46-year-old] man”. Names, either First Name or Last Name, are annotated together as a single entity mention when connected by a hyphen; if not, they are treated as distinct names.

The annotated corpus serves two purposes in the present study: (i) to investigate potential domain differences with respect to the prevalence and distribution of PHI, and (ii) to evaluate and compare the predictive performance of a model trained on a mixed corpus on different types of clinical notes with respect to the three dimensions mentioned above.

Results

When constructing the predictive model, the grid search for the optimal CRF hyperparameters led to the following choices: L2 regularization with a c value of 16 and a narrow (1+1) context window. The predictive performance estimates obtained through 10-fold cross-validation on the training set yielded a precision of 92.65%, a recall of 81.29% and an F1-score of 0.87.

The distribution of manually annotated PHI classes in the samples drawn from the various sub-corpora is depicted in Figure 1, where the total PHI count is shown above each bar. An inter-dimensional comparison shows that PHI are most prevalent in discharge notes and least prevalent in admission notes, as well as notes written by nurses. Overall, the most prevalent types of PHI are Health Care Unit, Last Name and Date Part. The least prevalent types of PHI are Phone Number, Age and Location.
In the speciality dimension, there are more PHI instances in oncology notes (242) compared to geriatrics notes (199) and orthopaedics notes (158). Here, Last Name and Health Care Unit are generally the most prevalent PHI types, although the proportion of Health Care Unit mentions is smaller in oncology notes. Dates, both Full Date and Date Part, are particularly prevalent in oncology notes, with around 46% of PHI mentions falling into these two categories. Phone Number mentions are non-existent in the oncology notes but amount to around 6% of PHI in geriatrics notes.

In the heading dimension, there are considerably more PHI instances — more than double, in fact — in discharge notes (302) compared to daily notes (148) and admission notes (123). Here, the generally most prevalent PHI types are Health Care Unit and Date Part. In admission notes, the distribution of PHI types is heavily skewed, with Health Care Unit (39%) and Date Part (27%) representing the largest classes. The PHI distribution is rather less skewed in daily notes and discharge notes. Names, both First Name and Last Name, are fairly common in these two types of notes, comprising around 30% of PHI mentions, compared to around 13% in admission notes. Dates are also common in all three note types but especially in the latter two. A difference between daily notes and discharge notes is that the latter contains considerably more Full Date mentions (22%) than the former (4%), while the former contains more Date Part mentions (37% vs. 20%).

In the profession dimension, differences with respect to PHI prevalence is rather less pronounced; however, there are more PHI mentions in physician notes (154) than in physiotherapist notes (131) and nurse notes (123). Here, the generally most prevalent PHI types are Last Name and Health Care Unit. The distribution of PHI types is most skewed in physiotherapist notes, with names, both First Name and Last Name, making up around 58% of mentions. Names are also prevalent in nurse notes, a little less so in physician notes but they still make up around 50%. Besides names and mentions of Health Care Unit, physicians appear to have a propensity for writing dates — making up around 35% of all PHI mentions — to a larger extent than do nurses and physiotherapists (less than 30%). Mentions of Age are generally rare; however, they do make up 5% of PHI mentions in physician notes.

The predictive performance — in terms of precision, recall and F1-score — of the CRF model trained on the pre-existing corpus was then estimated on the nine sub-corpora. Given the rather small sample size, in particular w.r.t. to certain PHI classes, the predictive model is here only evaluated for its ability to detect any PHI, which is done by merging the labels post prediction. The performance scores obtained on the three sub-corpora belonging to different specialities are shown in Figure 2. The differences in performance across the three specialities are rather small, with F1-scores ranging from around 0.70 to 0.75. The best performance is obtained on oncology notes (F1: 0.74), primarily as a result of the relatively high precision (89.93%).

The performance scores obtained on the the three sub-corpora comprising clinical notes written under different headings are shown in Figure 3. The predictive performance is generally lower in these sub-corpora, while the differences are somewhat more pronounced: the best performance is obtained on daily notes (F1: 0.69) and the worst performance is obtained on admission notes (F1: 0.57). The difference between precision and recall is moreover even greater than was observed for clinical notes produced in different clinics: precision is rather high (up to 85.00%, in admission notes), while recall is low (as low as 42.86%, also in admission notes).
The performance scores obtained on the three sub-corpora comprising clinical notes written by clinicians in different professional roles are shown in Figure 4. Here, a considerable difference in predictive performance is observed between nurse notes ($F_1: 0.77$), on the one hand, and physician notes ($F_1: 0.62$) and physiotherapist notes ($F_1: 0.62$), on the other.

![Figure 4 - Predictive performance estimates w.r.t. the ability to detect PHI in clinical notes written by different professions](Image)

In general, the predictive performance is markedly lower in comparison to the cross-validated estimates obtained on the training corpus. The $F_1$-scores range from 0.57 (admission notes) to 0.77 (nurse notes). Precision is invariably higher than recall: precision ranges from 76.40% (physiotherapist notes) to 91.01% (nurse notes), while recall ranges from 42.86% (admission notes) to 66.94% (nurse notes).

**Discussion**

The manual annotation of PHI revealed considerable differences with respect to PHI prevalence across the various sub-corpora. Insights into the prevalence and distribution of PHI in different types of clinical notes are useful for directing automatic de-identification efforts and can, for instance, be exploited when creating annotated corpora for learning predictive models. In a previous study [11], we estimated PHI density by applying a predictive model to various types of clinical notes, which comes with the advantage of being able to utilize large amounts of unannotated data; the downside of such a method, however, is that classification errors are not directly taken into account. Manual annotation, as was conducted in the present study, is less prone to errors but requires considerable effort in order to obtain sufficiently large samples. The two methods can, to some extent, be validated by studying to what extent they agree with each other. The results obtained in these two studies show that the methods are generally in agreement. For instance, discharge notes exhibited the highest PHI density according to both methods, which also revealed high PHI densities in geriatrics and oncology notes. The lowest PHI density was observed in admission notes according to both methods. There are of course also disagreements, e.g. concerning the prevalence of PHI in nurse notes. Many of the observations made in this study with respect to intra-corpus PHI class distributions are also in agreement with the ones made using the method that estimates PHI density based on larger amounts of (unlabeled) data.

Differences with respect to the prevalence and distribution of PHI can, in part, be explained by domain or genre differences. For instance, the informality of daily notes is expressed through the prevalent use of First Name and Date Part. In contrast, discharge notes are more formal, which is reflected in the prevalent use of Last Name and Full Date. The high prevalence of PHI in discharge notes is moreover not surprising given that the healthcare process is in some ways summarized therein, which means that, for instance, health care units and physicians that have been involved tend to be named.

The predictive model dropped in performance, in comparison to cross-validated estimates obtained on the training corpus, when applied to the nine sub-corpora. A performance drop can be expected since the cross-validated estimates obtained after an extensive grid search for optimal model hyperparameter values is likely to be somewhat optimistic. It is also to be expected given differences between training and test data, resulting, for instance, in the system having to deal with out-of-vocabulary words. With that in mind, you would expect slightly better predictive performance to have been obtained on the orthopaedics notes since such notes were also included in the training corpus; however, that was not the case. Nevertheless, the more interesting finding based on these experiments is that the observed predictive performance differed substantially, in some cases, between different types of clinical notes. The most notable instance of this phenomenon occurred between nurse notes, on the one hand, and physician notes and physiotherapist notes, on the other. The relatively high performance obtained on nurse notes can, to some extent, be attributed to their low type-token ratio (0.008) and short sentences (8.1 tokens on average). However, other domain differences must be sought for a fuller explanation of the observed differences in predictive performance.

The drop in predictive performance when training a model on one corpus and applying it to other corpora from different domains calls for domain adaptation methods. In the absence of the resources needed for creating a large and representative corpus of clinical notes manually annotated for PHI, such methods would be critical in avoiding the kind of performance drops observed in this study. The relatively low predictive performance obtained on discharge notes is particularly alarming given the high prevalence of PHI therein.

**Conclusions**

In this study, the prevalence and distribution of protected health information in various types of clinical notes was investigated, revealing considerable differences, including an especially high prevalence of sensitive information in discharge notes. The ability of a predictive model, trained on data drawn from a number of clinics, to generalize to new domains and accurately detect protected health information in various types of clinical notes was moreover assessed. This experiment demonstrated a substantial drop in predictive performance — as well as considerable differences with respect to diverse and heterogeneous clinical notes — when the model was applied to hitherto unseen types of notes, emphasizing the need for domain adaptation. The insights gained into the effects of domain differences, in particular with respect to the prevalence and distribution of protected health information, on predictive performance on heterogeneous clinical notes are valuable for future development of automatic de-identification methods.

\(^2\) PHI prevalence is used in the current study since an equal number of sentences is sampled from each sub-corpus; in this case only minor differences w.r.t. the number of tokens exist.

Abstract

Clinical risk prediction of acute coronary syndrome (ACS) plays a critical role for clinical decision support, treatment management and quality of care assessment in ACS patients. Admission records contain a wealth of patient information in the early stages of hospitalization, which offers the opportunity to support the ACS risk prediction in a proactive manner. However, ACS patient risks aren’t recorded in hospital admission records, thus impeding the construction of supervised risk prediction models. In our study, we propose a novel approach for ACS risk prediction, which employs a well-known ACS risk prediction model (GRACE) as the benchmark methods to stratify patient risks, and then utilizes a state-of-the-art supervised machine learning algorithm to establish our risk prediction models. The experiment was conducted with a collection of 3,643 ACS patient samples from a Chinese hospital. Our best model achieved 0.616 accuracy for risk prediction, which indicates our learned model can achieve a better performance than the benchmark GRACE model and can obtain significant improvement by mixing up patient samples that were manually labeled risks.

Keywords:
Risk Assessment; Acute Coronary Syndrome; Supervised Machine Learning

Introduction

Acute coronary syndrome (ACS) refers to a group of conditions where, due to decreased blood flow in the coronary arteries, part of the heart muscle is unable to function properly or dies \[1, 2\]. Clinical risk prediction of ACS, as an essential procedure in patient care delivery, plays a critical role for clinical decision support, patient treatment management, as well as the quality of care assessment \[1, 3\]. For a long time, a lot of studies have focused on this important topic and established a lot of ACS risk prediction tools such as GRACE \[4\], TIMI \[5\], Pursuit \[6\] and Framingham \[7\], which have illustrated a competitive performance in real clinical scenarios. Although useful, these tools have drawbacks such as limited consideration of risk factors, a long period of data collection, and strict inclusion/exclusion criteria \[3\].

Nowadays, more and more information systems are implemented in hospitals, which generate a large volume of electronic medical records (EMR) to support the study of medical informatics. In particular, admission records that capture a large amount of patient information in the early stages of hospitalization make it possible as brand-new media for ACS risk prediction. In our previous work \[8\], we have proposed a Rule-based Medical Language Processing method to extract features from admission records. However, patient risks are not explicitly recorded in their admission records, which impedes our employment of supervised machine learning algorithms to build our risk prediction models. Therefore, we address this issue in our study by applying a well-known ACS risk prediction model, i.e., GRACE, which was established by the full spectrum of patients, as our benchmark method to stratify each patient sample into 3 risk levels, i.e., low-, medium- and high-risk levels, based on a pre-selected set of risk factors identified in the GRACE model and extracted from the admission records. As such, the corresponding class label, i.e., risk levels of patient samples, can be assigned to that patient. Thereafter, we employ three state-of-the-art supervised machine learning algorithms, i.e., Random Forest (RF), Support Vector Machine (SVM) and Logistic Regression with \(\ell_2\) regularization on the regression coefficients (\(\ell_2\)-LR), to build ACS risk prediction models. The experiments have been conducted on a real clinical dataset consisting of 3,463 patient samples collected from the cardiology department of Chinese PLA General Hospital. Experimental results demonstrate the feasibility of our novel approach for ACS risk prediction.

Methods

Data

A total of 3,463 admission records were collected from the Cardiology Department of the China PLA General Hospital, which covers heterogeneous aspects including demographics, chief complaint, medical history, lab test and specific inspection, etc. These data can be used to provide ACS risk prediction service at an early stage of hospitalizations. The average length of stay (LOS) is 8.20 days, while some patients take a very short time, i.e., only 1 day in the hospital, and others take much longer, i.e., more than 3 months in the hospital, which implicitly indicates the diversity of patient conditions in the treatment process. In our previous study, we employed a Rule-Based Medical Language Processing (RBMLP) method to extract features from the free text of admission records and a simple regular expression to extract vital signs and lab test results that are in a structured format to support the construction of ACS risk prediction models. A total of 268 features were extracted using the RBMLP which covered 9 different categories. The evaluation of feature extraction results has been implemented depending on manually labeled features of 100 randomly selected patient samples by an experienced clinical engineer. The precision, recall, and F-score are 98.56%, 95.26% and 96.88%, respectively, which indicate that the feature extraction results can effectively reflect the patient conditions. Table 1 shows the summaries of extracted patient features.
The case study was performed in the Cardiology Department at the Chinese PLA General Hospital. Prior approval was obtained from the data protection committee of the hospital to conduct the study. Patient data were anonymized in this study and in this paper.

Benchmark dataset

While an admission record contains valuable patient information like demographics, medical history, lab test and specific inspection, and diagnosis codes, etc., the patient’s risk score, as an important clinical outcome indicator in ACS treatment processes and necessary information for constructing training samples of ACS risk prediction, is not directly available in the records. To address this problem, we applied a well-known ACS risk scoring model, i.e., GRACE [4], as the benchmark method to determine the risk score of an ACS patient by referring to his or her admission record. GRACE is an international observational database designed to reflect data from an unbiased population of ACS patients. It is established by the full spectrum of ACS patients (ST-segment elevation myocardial infarction, non-ST-elevation myocardial infarction, and unstable angina). It has been proved that the model can provide excellent ability to assess the patient’s risk [9]. In particular, we stratified each ACS patient sample into one of three risk levels (i.e., low-, medium-, and high-risk levels) based on the calculated GRACE score [10].

Note that GRACE scores are not presented in our original dataset, and were calculated on a pre-selected set of risk factors extracted from admission records by the proposed methods presented in our previous work. However, missing data is a problem intrinsic in free text information extraction and our work is no exception [11]. While the most common way to handle the missing data is to exclude or discard the data, it is not suitable for our work because of the amount of missing value of our data, and it may also create biased estimates [12]. To overcome the limitations, we employed three strategies based on the different risk factors in the GRACE model. Table 2 summarizes the strategies we employed for each risk factor. For Heart rate and Systolic blood pressure, we replaced the missing values with mean values (Strategy 1), and we employed multiple imputations [13] (Strategy 2) to impute the missing values in creatinine and elevated cardiac markers, and for the ST-segment deviation, Killip class and cardiac arrest at admission, we considered the patients were normal if we didn’t extract the information indicating their abnormalities (Strategy 3). While the missing value percentages for Strategy 3 risk factors seem to be huge, it is effective as physicians recorded only the activities deviating from normal (charting by exception). Based on the strategies to handle missing values, we obtained the completed imputed dataset. Accordingly, we can then build our risk prediction models from admission records and their corresponding risk levels based on GRACE. We can then build our risk prediction models using well-established machine learning algorithms with their predictive accuracy on the hold-out samples. In this study, three representative supervised machine learning classifiers, including Random Forest (RF), Support Vector Machine (SVM) and Logistic Regression with l1 regularization on the regression coefficients (l1-LR), were selected and compared to each other due to their demonstrated predictive performance and their wide usage in the recently published research literature. All classifiers were multinomial models (eligible for three classes: low-risk, medium-risk and high-risk). A 5-fold cross validation was performed on each classifier. We repeated the learning process 10 times to measure the average performance and the 95% confidence interval of each classifier. What follows is a brief introduction to the employed algorithms as clinical risk prediction tools:

- SVM is one of the most popular classification models based on constructing a hyper-plane or set of hyperplanes in a high- or infinite-dimensional space to classify [14]. In this study, RBF kernel was employed to build the non-linear SVM classifier with parameters, i.e., Cost and Gamma, determined by cross validation [15].
- RF is an ensemble learning method that operates by constructing a multitude of decision trees and outputting the class that is the mode of the classes of the individual trees [16]. In our study, we set 1000 as the number of trees in the forest and the square root of the number of features as the number tried at each split [16].
- l1-LR is the LR with a lasso penalty factors on the regression coefficients [17]. l1-LR has been widely used for many classification problems, particularly ones with many features. It is well-known that regularization is required to avoid over-fitting, especially when there are a large number of parameters to be learned and can be used as feature selection methods [17]. In our study, we determined the parameter, i.e., Lambda, depending on cross validation.

To evaluate the performance of the learned models, we employed the receiver operating characteristic (ROC) curve and the area under the ROC curve (AUC) to evaluate the learning algorithms. Note that the ROC curve can only evaluate the performance of binary classifiers, we plot three ROC curves, i.e., low-risk or not, medium-risk or not and high-risk or not, for each model using the one-vs-rest approach. We also calculated the micro- and macro-averaged ROC curve for each model to show the overall performance. Moreover, we calculated the prediction accuracies for each model and employed Wilcoxon signed-rank test to compare the differences between GRACE and the learned models. All
model constructions and statistical analyses were completed using R version 3.2.1 (R Foundation for Statistical Computing) and Scikit-learn library [18] under Python version 3.5.1.

Experiments and Results

Benchmark dataset construction
According to our previous work, we have extracted patient features from their admission records using our RBMLP method. The summaries of extracted features are illustrated in Table 1. Based on the feature extraction results, we employed the well-known ACS risk prediction model, GRACE, as the benchmark method to label the risk levels to the patients in the data pool. In particular, we designed three different imputation strategies to overcome the missing value limitation. The summaries of labeled patient samples were illustrated in Table 3. After the benchmark dataset construction, 1,968, 1,054 and 441 patients were stratified into low-, medium- and high-risk levels, respectively.

### GRACE Items
- **Age (year)**
  - <40: 68 (1.96%)
  - 40-49: 443 (12.79%)
  - 50-59: 908 (26.22%)
  - 60-69: 866 (25.01%)
  - 70-79: 842 (24.31%)
  - ≥80: 236 (9.70%)

- **Heart rate (bpm)**
  - <70: 1,122 (32.40%)
  - 70-89: 2,164 (62.49%)
  - 90-109: 164 (4.74%)
  - 110-149: 13 (0.38%)
  - 150-199: 0 (0%)
  - ≥200: 0 (0%)

- **Systolic BP (mmHg)**
  - <80: 1 (0.03%)
  - 80-99: 35 (1.01%)
  - 100-119: 439 (12.68%)
  - 120-139: 1,897 (54.78%)
  - 140-159: 786 (22.70%)
  - 160-199: 299 (8.63%)
  - ≥200: 6 (0.17%)

- **Creatinine (μmol/L)**
  - 0-35: 11 (0.32%)
  - 36-70: 1,400 (40.43%)
  - 71-105: 1,706 (49.26%)
  - 106-140: 223 (6.44%)
  - 141-176: 60 (1.73%)
  - 177-353: 22 (0.62%)
  - ≥354: 18 (0.52%)

- **Elevated cardiac markers**
  - 15 (648 (18.71%)

- **Killip class**
  - Class I: 3,220 (93.27%)
  - Class II: 134 (3.87%)
  - Class III: 88 (2.54%)
  - Class IV: 0 (0.03%)

- **Cardiac arrest at admission**
  - 0 (0.00%)

- **ST-segment deviation**
  - 15 (569 (16.43%)

Risk prediction model construction
We employed three representative supervised classification methods (i.e., RF, SVM and ℓ1-LR) described above under ‘Risk prediction model’, with datasets constructed by the RBMLP feature extraction methods in our previous work. And then, we employed metrics of ROC and AUC to evaluate the learned models. Considering that the ROC curve can only evaluate the performance of the binary classifier, we plot three ROC curves (low-risk or not, medium-risk or not and high-risk or not) for each model respectively. Then we integrated the model’s three curves into Micro- and Macro-Averaged ROC curve [18] to show the overall performance of the model. Furthermore, to analyze the influences of changes in sample sizes on the model’s AUC, we randomly selected the same proportion of samples from three risk levels. By the 10 times repetition of learning process under 10 different sample sizes, we averaged the 10 generated curves’ AUC under each sample size to form a curve with 95% confidence interval (CI). The left side of Figure 1 shows the ROC curves of each model and the right illustrates the AUC changes under different sample sizes. All three learned models achieved acceptable performance using the GRACE-labeled dataset, which indicates that our models obtained a good fitting degree with the GRACE model. (1-LR achieved best performances (0.98 in Micro-averaged ROC and 0.97 in Macro-averaged ROC). And moreover, the AUC of all learned models gradually ascended and became more stable along with the increase of sample size, which indicates that our learned models can achieve more competitive performance under a larger sample size.

Risk prediction model evaluation
As presented above under ‘Risk prediction model construction’, we have shown that our models can achieve a very high fitting degree with the GRACE model. In this section, we further evaluate the effectiveness of our models on ACS risk prediction, in comparison with GRACE via a small set of manually labeled ACS patient samples. As mentioned above, the risk labels of the training dataset are provided by the GRACE model. Although useful, it might introduce errors and noises during the risk labeling process via GRACE since the actual outcome of an ACS patient is unknown. A more reasonable method is to review an ACS patient’s progress notes in the hospital to check the outcomes of that patient. As such,
the actual adverse event label can be provided for that patient. Thus, it raises the question if we can learn a more effective and robust risk prediction model from an accurately labeled dataset. To this end, we randomly selected 500 patient samples from all 3,463 original patient records and then asked an experienced clinical engineer to manually provide risk labels of these patients by reviewing their progress notes in their hospitalizations. Then, we divided the manually labeled samples into 5 parts and each part was predicted by the model retrained based on the rest 4 parts and the other 2,963 (3,463-500) GRACE-labeled patient samples. To evaluate the performance of the benchmark GRACE model, our risk prediction models learned from both the GRACE-Labeled dataset (namely Models-GL), and the dataset mixed with Partly Manually Labeled patient samples (namely Models-PML). The accuracy of each model is computed and shown in Figure 2. In addition, we employed Wilcoxon signed-rank test to check the significant differences between the GRACE and the learned models. The experimental results are shown in Table 4.

![Figure 2 – Accuracy of each model for predicting the 500 manually labeled patient samples](image)

</table>

As shown in Figure 2, the GRACE model achieves 55.4% accuracy for the 500 manually labeled patient samples. It indicates that the GRACE model has a good discriminatory ability in predicting ACS patients’ risks. More surprisingly, all our models, i.e., RF, SVM and ℓ1-LR models, learned from the GL dataset and the PLM dataset to achieve competitive performance. In Figure 2, the prediction accuracy of the best model (i.e., RF-PLM) is 61.6%, and is higher than the accuracy obtained by the GRACE model. The Wilcoxon signed-rank test results proved the significant improvements of our models in comparison with GRACE. In addition, we compared the performance obtained from both Models-GL and Models-PML in terms of accuracy, to explore whether the prediction performance can be significantly improved from the manually labeled samples. As shown in Table 4, there are significant differences of Models-GL and Models-PML, in which we argue that the proposed approach can obtain better prediction performance from manually labeled patient samples.

The ability to analyze a large volume of EMR data in modern healthcare systems plays a vital role in the improvement of the quality of care delivery [19]. In this paper, we employed a well-known ACS risk prediction model, i.e., GRACE, as our benchmark method to automatically stratify 3,463 patient samples into low-, medium- and high-risk levels, respectively. In particular, three imputation strategies were presented to solve the missing value limitation in our dataset. Then, three competitive supervised machine learning algorithms were selected to construct our risk prediction models. Experiments have been conducted in a total of 3,463 ACS patient samples collected from a Chinese hospital to evaluate the performance of our models. By the evaluation of 500 manually labeled samples, our Models-GL achieved better performances than the GRACE model. The Models-PML obtained a significant improvement in comparison with GRACE and Models-GL, which indicates that the risk model’s performance can be elevated by the mixing of manually labeled patient samples.

However, there are still certain limitations in our current work. In this study, the labels in the training dataset are provided by the benchmark GRACE model. Note that, GRACE, as a prospectively studied scoring system, is not always effective in risk prediction in various clinical scenarios [20]. The intrinsic problem of free-text-extracted data, i.e., missing values, also made the labels that were provided by benchmark GRACE model less accurate, though we have employed imputation strategies to handle this problem. As indicated in our experimental results, incorporating manually labeled patient samples provided by experimented physicians into the training dataset can improve the performance of our models in ACS risk prediction. Thus, the better way to build a benchmark dataset is to retrospectively study medical cases to stratify ACS patient’s risks by experienced physicians. However, it is a tedious and time-consuming process for human evaluation on a large volume of patient samples. To this end, semi-supervised learning could provide a feasible solution since it can use ready-to-use unlabeled data to improve supervised learning tasks when the labeled data is scarce or expensive [21].

In this paper, we have presented a novel approach to utilize the well-known ACS risk prediction model, GRACE, as the benchmark for the establishment of improved models for ACS risk prediction. The experimental results show that our learned models can achieve a better performance than the GRACE model and obtain a significant improvement by mixing manually labeled patient samples into the training dataset, which illustrates a brand-new approach to risk prediction model construction using existing methods.

Abstract

The World Health Organization has declared Bangladesh one of 58 countries facing acute Human Resources for Health (HRH) crisis. Artificial intelligence in healthcare has been shown to be successful for diagnostics. Using machine learning to predict pharmaceutical prescriptions may solve HRH crises. In this study, we investigate a predictive model by analyzing prescription data of 4,543 subjects in Bangladesh. We predict the function of prescribed drugs, comparing three machine-learning approaches. The approaches compare whether a subject shall be prescribed medicine from the 21 most frequently prescribed drug functions. Receiver Operating Characteristics (ROC) were selected as a way to evaluate and assess prediction models. The results show the drug function with the best prediction performance was oral hypoglycemic drugs, which has an average AUC of 0.962. To understand how the variables affect prediction, we conducted factor analysis based on tree-based algorithms and natural language processing techniques.

Introduction

The World Health Organization has declared Bangladesh one of 58 countries facing acute Human Resources for Health (HRH) crisis [6]. Health care provider densities in Bangladesh are only 0.3 physicians and 0.28 nurses per 1,000 people. In comparison, the health care provider densities in Japan are 2.1 physicians and 7.9 nurses per 1,000 people.

Recently, artificial intelligence-based healthcare systems are highly regarded due to their success in diagnosis, prediction, and choice of treatment [3-5]. Karimi et al., [1] used a decision tree and support vector machine (SVM) to predict metabolic syndrome from 2,107 participants. Colubri et al., [2] developed a machine-learning pipeline for Ebola prognosis prediction that packages the best models into a mobile app that is available in clinical care settings. Kyushu University and Grameen Communications have conducted a study [7] into health management using information communication technology. The Portable Health Clinic (PHC) developed a package with medical sensors (e.g., blood pressure monitors, blood glucose meters, and urine tape) to provide immediate consultation with a remote doctor over Skype. Operators can use the system with minimal information technology literacy to provide health checkup services, even in rural areas. Following the tele-consultation, the remote doctor can give the patient an electronic prescription.

We predict the function of prescribed drugs, comparing three machine-learning approaches. The approaches compare whether a subject shall be prescribed medicine from the 21 most frequently prescribed drug functions. Receiver Operating Characteristics (ROC) were selected as a way to evaluate and assess prediction models. The results show the drug function with the best prediction performance was oral hypoglycemic drugs, which has an average AUC of 0.962. To understand how the variables affect prediction, we conducted factor analysis based on tree-based algorithms and natural language processing techniques.

Methods

Data collection procedure

PHC comprises a set of sensor devices in an attaché case, a data transmission system linked to a mobile network, and a data management application.

We provided a healthcare service for the study, including health checkups that used sensor devices in the PHC, data storage in a call center, a health report, and healthcare guidance according to the given individual, and a tele-consultation with a doctor in a medical call center. We conducted the study in five rural villages and five factories/offices in Bangladesh. During the first visit, after registration, the subjects received an ID card with a barcode. After completing a questionnaire, the subject underwent a health checkup using the sensor devices in the PHC. Qualified healthcare professionals performed both blood glucose and urine tests, and trained staff performed other tests.

We crosschecked the urine test results of the workers every two or three months because this test requires a visual assessment. Other devices, including blood glucose devices, display numerical results that do not require calibration among workers. The data were stored on an Android tablet and the main server in Dhaka. We implemented categorized results for four risk groups for PHC, which are green, yellow, orange and red, according to a rule-based triage algorithm, in which, local staff printed and explained to the subject. A booklet was provided to all subjects who are marked for health risk according
to test results. We provided telemedical intervention with a doctor in Dhaka for orange- and red-grade subjects. Because we selected sites from around Dhaka in the first year, subjects in the village and factories/offices around Dhaka were asked to undergo a health checkup one year later to assess the effects of the program.

After the health checkup, we provided telemedical intervention for orange- and red-grade subjects, via mobile network contact (Skype), with the medical call center in Dhaka. Because most areas in Bangladesh have Internet access (2G/3G), we brought laptop PCs or tablet PCs (iPad) with mobile routers to the checkup sites. The staff set up special rooms for teleconsultations at checkup sites and assisted subjects in their language with remote doctors in Dhaka. Doctors had access to the health checkup results via the Internet and could provide advice about disease management and encourage subjects to visit a clinic. Where required, the doctors could send a teleprescription for anti-hypertensive medication via the network. In our program, subjects who received a teleprescription could visit their local pharmacy to purchase medication.

PHC field study was conducted between July 2012 and March 2014 (first year: July 2012-February 2013; second year: June 2013-March 2014). In total, 16,741 subjects were assessed in the first health checkup and 4,543 were provided remote consultations. The remote consultation records, which contain information about chief complaints (CC), doctor advice, and e-prescriptions, were input in Bengali during the field study and then translated to English. Ethics Review Committee of Kyushu University Hospital has approved this study (Ethics Review Number: 24048).

Table 1 shows the classified function of medicine prescribed to more than 100 subjects. We identified 21 pharmaceuticals, and we predicted whether each drug has been prescribed.

Drug hierarchical structure

The chemical type of active ingredient may classify a drug or by the way, it is used to treat a particular condition. We use a four-layer hierarchical drug classification system based on a Bangladesh medicine database, which has information in English on Bangladesh medicines [8]. Figure 1 shows the hierarchical drug classification system.

“Drug Function” (Drugs for) and “Drug Class” are the first and second levels of the hierarchical drug classification system. Drugs used for the same purpose belong to the same “Drug Function” block and drugs that work in the same way belong to the same “Drug Class” block. “Generic Name” is the third level and is classified by the chemical type of the active ingredient. Many pharmaceutical companies market generic drugs, and these companies select a “Brand Name” (fourth hierarchy level) for their products.

In the PHC field study, health checkup prescription data is input and recorded as “Brand Name.” We added “Drug Function” information to the data by querying a Bangladesh medicine database using the brand name of each pharmaceutical [8]. Since a doctor’s diagnosis is not contained in the remote consultation record, “Drug Function” information can be considered an alternative way to understand a subject’s health problem.

Explanatory variables

We used 1,550 variables as explanatory variables to predict pharmaceuticals to be prescribed.

Basic information and measurement results (49 variables)

The subject profile contains gender, age, site ID (15 sites), site type (rural, suburban, or urban), and checkup date. Measurement items are waist, hip, waist-hip ratio, height, weight, BMI, systolic blood pressure, diastolic blood pressure, blood sugar (BS), BS type (postprandial or fasting), urine protein, urine sugar, urine urobilinogen, pulse rate, arrhythmia, body temperature and SpO2. Each measurement result is classified (four colors) using specific diagnostic rules we implemented for PHC [7]. These colors are also used as explanatory variables.

Interview sheet (50 variables)

Before receiving remote diagnosis by a doctor, the subjects were interviewed by local staff. The interview was conducted using an interview sheet. The interview sheet contains 31 questions about occupation, present symptoms, past diseases, medication, smoking, weight change, exercise, walking speed, eating behavior, sleeping habits, the desire to have a healthy lifestyle, drug allergies, and surgical history. Since some questions are given in a multiple-choice format and encoded to one-of-K coding, there are 50 variables in the sheet.
Chief complaint text (1,451 variables)

The remote doctor inputs the CC and it contains the primary symptoms identified by the patient. Punctuation marks and numbers in the CC are filtered in data preprocessing to simplify the variables. N-grams (n = 1, 2, 3, 4) are extracted from the CC text, and we counted the number of each n-gram where the frequency is greater than six (= 0.1% of the total record).

An n-gram is a contiguous sequence of n items from a given sequence of text or speech. For example, a 2-gram (or bigram) is a two-word sequence, such as “chest pain.” The extracted number of 1-grams (or unigram) was 346, and that of 2-grams, 3-grams (or trigram), and 4-grams was 611, 340, and 154, respectively. The total number of n-grams was 1,451. We placed all n-gram variables in brackets (e.g., back pain) to differentiate the CC variable from the measurement or interview variables.

Training/Testing Set Division and Evaluation

We divided the entire sample into a training set and a testing set at a ratio of 6:4 to evaluate the three prediction models. We constructed each prediction model using the training dataset and evaluated the accuracy of the model by calculating positive predictive value (PPV) and area under the curve (AUC) of the receiver operating characteristic curve (ROC) for each model using the testing set. We repeated this sequence 10 times and calculated the mean and standard deviation of the AUCs, as well as the variable importance.

Analysis methods

In our analysis, we generated three prediction models to determine whether the pharmaceutical for a specific “Drug Function” (“Drugs for”) was prescribed using 1,550 explanatory variables. These three prediction models were generated based on an SVM, Logistic Regression (with Tikhonov regularization), and GBDT. GBDT, as proposed by Friedman [9], produces a prediction model in the form of an ensemble of weak prediction models, typically decision trees. Since GBDT is a decision tree model, we also compute the importance of each variable, as well as the predicted probabilities of an input sample as the mean predicted class probabilities of the trees [10]. In this way, we can identify which variables are related to the prescription of each pharmaceutical relative to “Drug Function” and how the variables relate. The probabilities of prescribing a pharmaceutical to the subjects in the testing set at a ratio of 6:4 to evaluate the three prediction models. We divided the entire sample into a training set and a testing set at a ratio of 6:4 to evaluate the three prediction models. We constructed each prediction model using the training dataset and evaluated the accuracy of the model by calculating positive predictive value (PPV) and area under the curve (AUC) of the receiver operating characteristic curve (ROC) for each model using the testing set. We repeated this sequence 10 times and calculated the mean and standard deviation of the AUCs, as well as the variable importance.

Partial Dependence Plot

A Partial Dependence Plot (PDP) is a visualization method for high-dimensional functions proposed by Friedman [9]. A PDP is useful to visualize the relationship between functions. It plots the marginal effect of the selected variables by integrating out the other variables. Higher value “partial dependence” means higher percentage of ‘yes’ vote by all the weak learners (trees) of GBDT. Let $f(x)$ be the result of a predictor and let $x_i$ be a target explanatory variable. Then, $F_i(x)$ is expressed as follows.

$$F_i(x) = \frac{1}{N} \sum_{j=1}^{N} f(x_1^{(j)}, x_2^{(j)}, \ldots, x_{i-1}^{(j)}, x_i^{(j)}, x_{i+1}^{(j)}, \ldots, x_p^{(j)})$$  \hspace{1cm} (1)

We can interpret Equation (1) as the predicted mean effects of $x_i$ assuming that all subjects’ $x_i$ values are changed to a particular value for $x$. Since the same dataset, except for the target explanatory variable, is used to calculate $F_i(x_a)$ and $F_i(x_b)$ for $x_a$ and $x_b$, the difference between $F_i(x_a)$ and $F_i(x_b)$ shows the effect of changing the target explanatory variable from $x_a$ to $x_b$. In other words, $f(x)$ is a pure outcome against the explanatory variable $x_i$, that removes the effects of other explanatory variables [11]. We use the PDP to interpret the effect of the target explanatory variable.

Results

We built three models using the training set of the data with three different approaches including GBDT, Logistic Regression, and an SVM. We used these three models on the test set of data to predict whether each “Drug Function” is prescribed. With the prediction result, we computed mean AUC of ROCs of predicting each drug function. Then we compared the AUCs of three approaches. GBDT showed the best performance among the three models.

![Figure 2- Comparison of AUC of ROC curve of the three methods when predicting the top 21 drug functions](image)

Model Comparison

As shown in Figure 2, GBDT demonstrates better overall performance than the other two models, presumably because a non-linear relationship exists in medical data. The drug function with the highest AUC (Mean = 0.962, Range = [0.944, 0.969]) was Drugs for oral hypoglycemic. Other drug functions with a mean AUC greater than 0.9 were Drugs for Antipyretic Analgesics (Mean = 0.909, Range=[0.899, 0.916]), Drugs for Allergic Disorders (Mean = 0.914, Range = [0.895, 0.932]), Drugs for Asthma & Prophylaxis (Mean = 0.936, Range = [0.924, 0.949]), Drugs for Bacterial Infections (Mean = 0.969, Range = [0.887, 0.916]), Drugs for Hypertension (Mean = 0.916, Range = [0.881, 0.927]), Drugs for Iron Deficiency Anemias (Mean = 0.916, Range = [0.892, 0.929]), and Drugs for Neuromuscular Disorders (Mean = 0.904, Range = [0.887, 0.921]).

Important features

The prediction of drugs for oral hypoglycemic showed the highest AUC (0.962) among 21 most frequent drug function types. The 12 most important features for predicting drugs for
oral hypoglycemic are “bs,” “c BS” (rule-based triage result of blood sugar based on our diagnosis rules), “uSugar” (urine sugar tape result), “c usugar” (rule-based triage result of urine sugar based on our diagnosis rules), “uSugar” (urine oral hypoglycemic is due to the measurement variables and due to feature importance. The 12 most important features are measurement variables or rule-based triage variables generated by measurements.

The 10 times mean of AUC of predicting drugs for peptic ulcers, which is the most prescribed drug type, is 0.826 (95% CI = [0.812, 0.823]), relatively less than that of drugs for oral hypoglycemic. To better understand this difference, we generated the feature importance for the model for predicting drugs for peptic ulcers. The 12 most important features for predicting drugs for peptic ulcers are “[acidity],” “[pain],” “[pad]” (“peptic ulcer disease”), “[lbp]” (“lower back pain”), “[gastric],” “[abdominal],” “q203: Abdomen” (whether to check abdomen abnormalities as a subjective symptom in an interview), “[gastritis],” “[ache],” “weight,” “[in],” and “bs” (blood sugar). The CC variables are in brackets to differentiate them from measurement and interview variables.

Figure 3 and Figure 4 show the PDP of the top 12 features of these two types of drug functions.

**Figure 3- PDP of top 12 features when predicting drugs for oral hypoglycemic**

In contrast, predicting drugs for oral hypoglycemic relies on measurement variables (particularly BS). We aim to transform the prediction model into a field-deployable application to predict drug functions to support clinical decisions. A prototype program that takes sensor measurements and text information as input and outputs a list of positively predicted prescriptions has been implemented. In addition, a web application is currently under development for practical use.

**Discussion**

The prediction model based on GBDT has the highest AUC among the three approaches is supposedly because that logistic regression and SVM (with linear kernel used in this study) are linear models which can separate the data well when the variable of interest (in our case, positive or negative on each drug function) has the linear dependency from the predictors. However, in this study we used predictors such as term frequency of chief complaint text, of which dependency may be different from linear. Whereas, GBDT is able to discover more complex dependencies at the cost of more time for fitting, which may be the reason of GBDT outperforming the other two in this case. The results also suggest that CC variables and measurement variables play different roles in predicting various prescriptions. Predicting drugs for peptic ulcers relies on CC text rather than the measurement of things like BS, body temperature, etc.

**Figure 4- Partial dependence plot of top 12 features in predicting drugs for peptic ulcer**

The terms with brackets in Figure 3, such as “[acidity],” indicate that the descriptions of these terms in the CC text increases the risk of prescribing drugs for peptic ulcers.

In contrast, predicting drugs for oral hypoglycemic is due to the measurement variables and due to feature importance. The 12 most important features are measurement variables or rule-based triage variables generated by measurements.

Figure 4 shows that BS greater than 200 mg/dl increases the risk of prescribing drugs for oral hypoglycemic. Similarly, a BMI greater than 30 has the same effect.

**Figure 5- Comparison of the mean term frequency in different groups for the CC terms in Figure 4. The vertical axis represents the number of people with the specific term in their CC text, and the green and red bars represent subjects with and without peptic ulcer prescriptions, respectively. The ratios between these two groups are greater than 10 for the terms “acidity,” “pud,” and “gastric,” which also indicates that these terms are highly related to the prescription of drugs for peptic ulcers.**

Drugs for hypertension have 669 records and the prediction model for this drug function shows a relatively high AUC (Mean=0.92), similarly with the result of oral hypoglycemic drugs. By computing the feature importance of GBDT model, we found that the variables that affect the prediction significantly are diastolic blood pressure, systolic blood pressure, the triage color and age.

**Figure 6** shows the concept of the diagnosis/prescription prediction web application based on this study. After patient information is input and submitted, the information and output page are shown to a remote doctor. In the output, predictions with a predicted score greater than this subject’s score are listed to remind the remote doctor of specific health risks. It is listed by the order of each model’s PPV as in Figure 6. PPV is shown in the purpose of providing remote doctor an intuition of the reliability of each drug function prediction based on past data. PPV describes the probability that a patient with a positive test result is actually diseased. For example, if a patient’s data is input into the application and hypertension is listed as a health risk, the prediction model computed the score of prescribing drugs for hypertension is 0.7, then PPV of predicting existing data based on this score, 0.7, will be generated and shown as the probability of correctly prescribing for this person based on past data. This way
provides remote doctor an intuitive understanding on the health risks based on existing data.

Figure 5- Comparing the mean term frequency in different groups for the term CC in Figure 4

In this study, we employed a prediction model based on measurement data and CC data. However, for practical use of the prescription prediction application, models with only CC data can be used as symptom checkers for individual users rather than for clinical decision support. The development of a prescription model can be very useful to assist diagnosis and self-diagnosis to tackle the HRH crisis in developing countries.

Conclusion

In this paper, we have compared the results of three machine-learning approaches to predict whether a subject is prescribed pharmaceuticals among the 21 most frequently prescribed drug types. We extracted important factors related to prescribing each pharmaceutical and conducted factor analysis based on tree-based algorithms and natural language processing techniques. These important factors and the model can be put to further use to support clinical decisions. Although the goal is to build a reliable system that automatically prescribes drugs for patients, the model is also applicable as a clinical decision support tool, such as identifying potential health risks.

Conditional Density Estimation of Tweet Location: A Feature-Dependent Approach

Hayate ISO, Shoko WAKAMIYA, Eiji Aramaki

Nara Institute of Science and Technology (NAIST), Japan

Abstract

Twitter-based public health surveillance systems have achieved many successes. Underlying this success, much useful information has been associated with temporal and spatial information. For fine-grained investigation of disease propagation, this information is attributed a more important role. Unlike temporal information that is always available, spatial information is less available because of privacy concerns. To extend the availability of spatial information, many geographic identification systems have been developed. However, almost no origin of the user location can be identified, even if a human reads the tweet contents. This study estimates the geographic origin of tweets with reliability using a density estimation approach. Our method reveals how the model interprets the origin of user location according to the spread of estimated density.

Keywords:
Social Media; Geographic Mapping; Disease Outbreak

Introduction

The recent rise in popularity and scale of social media has created a growing necessity for social-media-based public health surveillance. The feasibility of such approaches has been demonstrated using various associated information, including temporal information [1-2] and spatial information [3-5]. Temporal information is associated with all tweets, but spatial information is often unavailable for privacy reasons. One report described that fewer than 0.5% of tweets include GPS information [6]. This problem has become an important motivation for many studies of location estimation [7-11]. Recent studies have elucidated the characteristics of geo-tagged tweets using various approaches. These include location specificity of user attributes such as gender and age [12], linguistic variation [13], temporal effects on location classification accuracy [14], population biases [15], and content-based geographic density of tweets [16]. Our study is aimed at exploring the content-based characteristics of tweet location (System estimated location vs. Geo-tagged location) further. We also investigate differences between the estimated results and the interpretability of human estimation (System estimated location vs. human estimated location). The motivating examples of comparison to humans are shown in Figure 1. Based on these examples, even a human would have difficulty estimating the precise location. However, by some clues, we were able to infer the tweet origin weakly. As this example shows, we can have an idea of a tweet’s general region of origin. Therefore, unlike previous studies aimed at estimating the concrete region, our task is to estimate the probability density of the origin location, which more naturally fits human understanding.

A recent study [16] was undertaken to estimate the location as a density estimation problem. Although their motivations resemble ours, this research represents the geo-location identifiability of a given tweet as a combination of word-specific or n-gram-specific Gaussian Mixture Model (GMM).

We summarize the contributions of this study as follows:

• We provide simpler and more reasonable approaches to estimate the geographic region of a tweet. Although an earlier study [16] estimated GMM in each word independently, our method handles tweet contents in a vector representation.

• We examine the relation between human inference and geographic biases of geo-tagged tweets.

• We objectively and quantitatively evaluate the differences between human and model inferences.

Figure 1 – Estimated geographic distribution of a tweet. “Gold” represents the true origin of the tweet and “Human” represents the human interpretation of the origin of user location from the tweet content.

Materials

Tweet Dataset

We collected 554,320 geo-tagged Japanese tweets for a week (July 15, 2012 – July 21, 2012). For our purposes, we extracted tweets that were posted by Official Twitter clients: Twitter for iPhone and Twitter for Android. Consequently, our corpus comprises 204,748 tweets.

To estimate the number of mixture components, we split tweets into a triplet of training, validation, and test data. We used 144,748 tweets for training data and 30,000 tweets each for validation and test data. This is the section where the authors describe the methods used at the level of detail necessary to convey the sample size, setting, procedure, datasets, analytic plan, and other relevant particulars to the reader.

Human Annotation Rule

To evaluate how our model interprets origin locations of tweets, humans annotated Japanese region (8-way) or prefecture (47-way) labels for 5,000 tweets that were sampled randomly from the test data. Tweet data with several granularity labels were annotated independently by two annotators. To avoid birthplace and residential place biases, we permitted rough searching for
the word included in a tweet to identify its origin location. The human agreement rate was 93.6%, as measured by 100 tweets sampled randomly from the annotated ones. Table 1 presents the results, which indicate the difficulty of this task, in which most tweets were not identified by humans. Furthermore, goodness-of-fit test results showed that tweets with a position were identified by human beings. Results also showed that the multinomial distributions by prefecture differ for learning data tweets.

### Methods

#### Word-Specific Gaussian Mixture Model

In an existing approach [16], the GMM has been used for geographic density estimation of geo-tagged tweets. Each tweet is converted to n-gram features consisting of the number of n-gram occurrences in a corpus and geographic coordinates (longitude and latitude) of n-grams. GMM applied for each n-gram \( w_j \) is defined as word-specific GMM as

\[
p(y|w_j) = \sum_{k=1}^{K} \pi_k N(y|\mu_k, \Sigma_k)
\]

here \( y \in \mathbb{R}^2 \) represents geographic coordinates (latitude and longitude), \( w_j \) represents the word indexed in \( j \), \( \pi_k \) is the weight as the word \( w_j \) is assigned to the \( k \)-th mixture component, and \( N(y|\mu_k, \Sigma_k) \) is a multi variate Gaussian distribution with mean \( \mu_k \) and covariance \( \Sigma_k \).

After estimating GMM for each n-gram, the weighted sum of word-specific GMM is combined as

\[
p(y|x) = \sum_{j=1}^{J} \pi_j p(y|w_j)
\]

Where \( x = \{w_1 \ldots w_j\} \) represents the words in a tweet, \( \pi_j \) is the weight of the GMM on the word \( w_j \).

For the formula, it is important to ascertain the weight of each GMM \( \pi_j(w_j) \). To date, most methods calibrate parameters for improving the prediction accuracy, but they merely consider the geo-location identifiability of n-grams to adjust weights. These approaches also merely consider whether a specific word is included or not. They do not consider the meanings of the respective tweets.

In contrast, this study applies Gaussian Mixture Regression, which allows expansion of word-specific GMM further by ascertaining weights of tweet GMM automatically from joint probability distributions of a tweet and geo-location. Consequently, we can impose any kind of feature to our model.

### Feature-Dependent Density Estimation

To represent our location density model, we use Gaussian Mixture Regression (GMR) [18], which is formalized by a conditional distribution of a jointly estimated Gaussian Mixture Model (GMM).

Our model need not prepare a specific evaluation index for feature-dependent weight estimation. We can derive the weight of two-dimensional GMM from jointly estimated GMM. Therefore, we designate our model as feature-dependent. Depending on given feature vectors, the feature of GMR varies the mixture of weights and each component of Gaussian location and variances. Figure 1 presents examples of conditional geographic density of two tweets.

To obtain the GMR results, we first estimate the joint probability \( p(y|x) \) of \( p \)-dimensional tweet representation and two-dimensional Gaussian Mixture Model [17]. Then conditional distribution \( p(y|x) \) of geo-location \( y \) for a given tweet \( x \) can be derived analytically from the joint distribution \( p(x,y) \) as follows:

\[
p(y|x) = \frac{p(y|x)}{\int_p p(y|x)dx} = \frac{p(x,y)}{p(x)} = \frac{\sum_{k=1}^{K} \pi_k N(x|\mu_k, \Sigma_k)}{\sum_{k=1}^{K} \pi_k N(x|\mu_k, \Sigma_k)}
\]

where

\[
\pi_k = \frac{\pi_k N(x|\mu_k, \Sigma_k)}{\sum_{k=1}^{K} \pi_k N(x|\mu_k, \Sigma_k)}
\]

The key point of GMR is that the weights of mixture parameters are changed flexibly depending on the feature vector \( x \). Consequently, the tweet’s vector representation defines the two-dimensional GMM from jointly estimated GMM.

Our model need not prepare a specific evaluation index for our model. As described in the paper, we use a continuous word vector learned by fasttext [19] to compress the dimensions of our tweet dataset. We compose a vector representation of tweet by averaging all the word vectors in tweets.

**Results**

To compare our model with human inference, we evaluated our model through several perspectives.

First, we calculated the distance between our model density and the origin of tweets in a different identifiability dataset such as the prefecture level or region level. We choose the mode value of the estimated distribution as the estimated location and we got the city name from estimated geographic coordinates using Google Map API.

As a baseline method, we used the regularized linear regression method, Elastic-Net [20]. We optimized the baseline model using the validation set.

Our first results are presented in Table 2 and 3. Although our model performs worse than the baseline model, our model monotonically improves prediction performance through human inference improvement.

Second, we comprehensively investigated cases in which our model revealed a result similar to a human’s inference, when it failed to estimate origin locations, and when it outperforms human inference. Our characteristic examples are presented in
bicides of geo-tagged tweets. We examine estimated GMM in each word independently, our method the geographic region of a tweet. Although an earlier study [16] provide simpler and more reasonable approaches to estimate perspective for estimation of the tweet posting origin. We demonstrated that GMR provides a new approach classification approach, we misclassified this tweet, but it is apparent that our method estimates the distribution across both prefectures.

Our model incorporates the uncertainty of the user location estimated from tweet contents. We ascertained that GMR is more reasonable to cover a wider range of class such as a prefecture or region than classification approaches for a difficult tweet to identify the geolocation. To improve the model validity further, feature vectors have an important responsibility. Although this research only employs the textual information for geolocation estimation, the many previous researches empower the geolocation performance via classification. We will further explore which feature has good effects for estimating the tweet’s uncertainty.

In addition, we will apply our model for non-geotagged infectious diseases related tweets such as Influenza [2] to explore the regional trends of the infectious diseases.

### Conclusion

In this study, we demonstrated that GMR provides a new perspective for estimation of the tweet posting origin. We provide simpler and more reasonable approaches to estimate the geographic region of a tweet. Although an earlier study [16] estimated GMM in each word independently, our method handles tweet contents in a vector representation. We examine the relation between human interpretability and geographic biases of geo-tagged tweets.

Analysis of the Existence of Patient Care Team Using Social Network Methods in Physician Communities from Healthcare Insurance Companies

Márcia Ito, Ana Paula Appel, Vagner Figueredo de Santana, Luis G. Moyano

*IBM Research, São Paulo, SP, Brazil,
Department of Statistical Physics and Complex Systems, CONICET and Facultad de Ciencias Exactas y Naturales, Universidad Nacional de Cuyo, Mendoza, Mendoza, Argentina

Abstract

Care teams are formed by physicians of different specialties who take care of the same patient. Hence, if we find physicians that share patients with each other probably they configure an informal care team. Thus, the objective of this work is to explore the possibility of finding care teams using Social Network Analysis techniques in physician-physician networks where the physicians have patients in common. For this, we used healthcare insurance claims to build the network. There was the agreement on the metrics of degree and eigenvalue and of betweenness and closeness, also physicians with the 5 highest eigenvalues are highly interconnected. We discuss that the analysis of the physician-physician network with metrics of centrality is promising to reveal informal care teams. The high potential in calculating these metrics is verified from the results to evaluate member’s performance and with that how to take actions to improve the work of the team.

Keywords:
Data Mining; Patient Care Team; Quality of Life

Introduction

The control and management of chronic diseases are one of the greatest challenges of health and economic development in the 21st century as they are directly related to the population quality of life as well as to world productivity and spending. It is estimated that annually approximately 16 million people die prematurely before the age of 70 due to chronic diseases. There is also a loss of US $ 7 trillion in health productivity and spending over the next 15 years if no action is taken [1]. Chronic patients usually have the main diagnosis and other associated diseases requiring care by more than one medical specialty as well as other professionals who guide them in changing their behaviors as nutritionists and physiotherapists, for example. Professionals who care for the same patient form a team called care team. Coordinating the care activities of these professionals is essential to optimize the use of health resources, called care coordination. In addition, according to Owens[2], the approximate expenditures of a patient in whom there is no coordination of care is 75% higher than those who count on this team. The author also suggests that by improving care coordination, patient costs can be reduced by 35%. The concept of patient health management through coordinated care teams has been explored by several authors since the late 1960s. Care coordination aims to reduce the fragmentation of care and improve delivery of health services. Thus, there are several efforts to implement this type of program [3]. Studies[4],[5] indicate that successful programs are those in which long-term, trusting relationships are built between the patient and the care team and among the members of the care team. Collaboration among members of a care team is the most important feature as it allows: (1) planning the treatment in a shared way, (2) facilitating decision making, (3) defining the objectives of patient care, (4) coordinating in a transparent way in which each member assumes responsibility for his / her performance with the patient, (5) working cooperatively, and (6) facilitating communication among the members [6],[7],[8].

Since 1995 and with a considerable increase in the last years we found research that uses the techniques of SNA (Social Network Analysis) to evaluate the impact of networks of health professionals in hospitals [9],[10],[11],[12],[13],[14]. At the outset, these studies aimed to verify if it was possible to extract the network of physicians through the existing data in hospitals and to analyze improvements in the quality and safety of the patient [9]. More recently, there are studies that look for metrics and indicators in these networks that relate the network of physicians to costs and/or re-hospitalizations in hospitals [10],[11],[13],[14]. The conclusion from these papers is that the more that physicians collaborate with each other the costs tend to be lower. In this case, they used the calculation of density, degree, and betweenness. Readmission in hospitals can be seen by the density in which hospitals with a high number of medical communities have a low readmission of their patients [10]. Another study presents how to find medical errors and frauds in health insurance companies [12]. However, we haven’t found any work using SNA techniques that focuses on the relationship between physicians who have common patients who are not hospitalized. Thus, this study aims to explore whether it is possible to find care teams in networks of physicians from health insurance company claims and the possibility of using centrality metrics to analyze the interaction between these informal care team members.

Materials and Methods

Source Data

Health insurance companies generate a large number of data as products of their daily operations. Operations in this area produce a considerable amount of data, specialty, transactional, and also other forms of data, such as demographics, service provider location, and other essential data to accurately carry forward all business processes. These data are related to their demands, such as the claims that are the information that generates the payments to be made to the providers of health services. The claims inform all the details about the procedures and consultations carried out by the providers, such as the professional who carried out the procedure, the procedure itself, and the insured who received the procedure among others.
In this paper the definitions used, from this moment on, are:

- **Insured**: represents in the database provided, each of the individuals who used health insurance services and who at times can be referenced as a patient;
- **Physician**: represents each of the physicians who provided services or are registered as such in the source database;
- **Provider**: represents healthcare institutions that provide services to insurances and in which physicians assist the insured.

The data analyzed in this study correspond to the claims originated in operational processes of a large Brazilian health insurance company. The 18-month claims that cover the period from January 2013 to June 2014 were provided. The data set includes medical procedures performed throughout Brazil and all claims paid by the insurer and corresponding to a total of 108,982,593 claims, this means that in average the health insurance company processes almost 300,000 claims per day. The rationale of using this data resides not only because of its volume but also because it represents the main and more complex operation of the health insurance company. Permission to use the data for the purpose of the research was made through a contract between both parts (research department and the health insurance company). Before the anonymization of physicians and patients, the data was cleared (withdrawal of invalid registrations in Regional Medicine Council). In the original data we had information about 279,085 physicians, being 81% valid (related with 73% of claims); by valid we mean that the physician register was well formed and the number informed to the provider was valid. Moreover, we had information about 2,243,198 patients and 26,033 providers.

A common situation in Brazil about physicians and service providers is that some providers use one or a few physician IDs to register all the claims to the health insurance company. This fact occurs when only one physician is registered in the insurance company and can distort the data interpretation, affecting the quality of the results. Thus, in order to identify provider-physician relationships that are anomalous, we selected providers that are strongly related to some physicians. We consider providers with 90% of their relationship with one physician that has a large number of claims. In this selection, we removed 500 physicians (about 0.22% from total) from our data in order to prevent any misleading in the interpretation. After this selection, we had 12,924 providers connected with 219,675 physicians, that pair provider-physician which were analyzed in this project. Still related to the data, two important aspects are related to data distribution considering states and physician specialties. First, about country states, we have around 25% of the data without state information. This proportion becomes bigger when we look at the data as a graph since to consider the relationship between physicians the missing value of state in one or both nodes (physicians) invalidate an important piece of our analysis, i.e., the connections between physicians.

Finally, the specialty is another important information to explain the relationship between the physicians, because when we find a relationship between them of related specialties, we can conclude that they form an informal care team of the patients in common. However, because of the large amount of missing values and no specified specialty, the use of this information was limited. In the database table with information about physicians, we had 658,543 tuples that belong to the physicians that work with the health insurance company. Among these, 436,981 (66%) are active physicians (this means that they are active in the company's database and their registries are valid in the Regional Medicine Council) and only 29.3% have the specialty information.

**Mapping Claim Data as a Graph**

Health insurance claims data may be mapped in graph form by considering the healthcare professional as a node (of a certain type), patients also as nodes (of a different type), and establishing a link whenever there is a claim mentioning both entities (Figure 1). The resulting graph is an example of a bipartite graph, where there are several types of nodes and there are no links between nodes of the same type. Moreover, additional bits of information in the data may be included in the graph in the form of weights in the links (such as the timestamp, the service provided or the expense amount), or as attributes in the nodes (as the patient demographics information or the medical specialty of the healthcare professional). Both weights and attributes may be represented in a graph layout by mapping their values to colors or sizes in the case of nodes, or colors and widths in the case of links. In this work, we focus on the relative influence of the physicians' activity in the relationship among the physicians in the health insurance company network. Two physicians are considered related if they have a common patient (a patient that had a consultation with both physicians). This does not indicate a direct relationship between the physicians but if they have a very large number of common patients (represented as an outlier) there is a high probability that physicians have some kind of professional relationship, for example, they have a similar profile, same provider, work nearby, a similar education background, etc. For this, we build a graph \( G = (V, E) \) physician-physician, where the \( |V| = N \) denote the set of nodes that are physicians and \( |E| = M \) denotes the edges, which means physicians that have consultation claims with patients in common, \( e_k \in E \quad e_k = \{(v_i, v_j) | v_i, v_j \in V \} \).

The fact that physicians attend to the same patient does not necessarily mean that there is collaboration between them in the treatment of the patient, but if it is very recurrent it may indicate this possibility. On the other hand, if the number of patients common among them is high there is the probability that they have some kind of professional relationship, for example, to be the team care of those patients.

![Figure 1](image.png)  
*Figure 1 – Example of the patient-physician network, which can be used to map the relationship between physicians*

**Results**

First of all, centrality metrics were selected to analyze the relative importance of physicians in the network and if there are any possible collaborations among them in the treatment of patients:

- **Degree**: The importance of the physician is proportional to the number of patients shared with other physicians.
• **Eigenvalue:** The higher the number of shared patients with other important physicians, the more important the physician is considered. If the physician shares a large number of patients but with physicians not considered important in the network, the physician is not considered important [15].

• **Betweenness:** Taking into account that physicians can be influential to other physicians that are closer, for example, when a physician indicates another physician to his/her patient, it is possible to define a metric that captures this proximity [16].

• **Closeness:** The physicians can be related by the amount of other physicians that are known among each other, indirectly, without their knowledge [9]. Thus, it is possible to compute the degree of separation between physicians by considering the number of physicians that are needed to connect two physicians.

We used all these four metrics to the same network including all the states, considering also how they change over time. We divided the whole period into intervals, considering quartiles. In Table 1, we can see that the number of physicians and patients that we use in our analyses. The results allow associating of the metrics to all physicians connected to a main group (major related component) within the quartiles time interval (Q2 to Q4 of 2013 and Q1 to Q2 of 2014).

### Table 1 – Number of physicians and patients analyzed by quartile

<table>
<thead>
<tr>
<th>Quartile</th>
<th>Q2 2013</th>
<th>Q3 2013</th>
<th>Q4 2013</th>
<th>Q1 2014</th>
<th>Q2 2014</th>
</tr>
</thead>
<tbody>
<tr>
<td>Physician</td>
<td>8,443</td>
<td>8,668</td>
<td>7,870</td>
<td>8,273</td>
<td>8,273</td>
</tr>
<tr>
<td>Patient</td>
<td>215,252</td>
<td>225,708</td>
<td>197,018</td>
<td>213,635</td>
<td>203,116</td>
</tr>
</tbody>
</table>

The resulting ranking depends on the used metric, but there is still a degree of correlation among the metrics. For instance, for Q2 of 2014, 14 physicians from top 20 using **eigenvalue** as a metric, are the same in the others metrics, showing us that the four centrality measures are consistent. Given that all the metrics capture the importance of the physicians in a similar way. In general, we have a metric concordance between 10% and 20% of top 100 physicians, which is high considering that we have almost 8k physicians.

Figure 2 shows the degree distribution of the physician-physician network. As we can see, the decay is much smaller than an exponential curve which is the case of a random graph and a little more curve than a straight line that is a perfect power law. So, it shows that this behavior is similar to a graph of a social network than to a synthetic graph, meaning that the behavior of physicians is not random but strongly dominated by correlations such as patients returning to the doctor, similar specialties, proximity to providers, etc. [17] This supports our approach in using SNA methods to analyze the presented data.

![Figure 2 - Degree distribution of the physician-physician Network](image)

One important characteristic is the possibility of following the physician's evolution related with these metrics. In Table 2 we show the top 10 physicians over the period and considering all states using eigenvalue. As we can see some physicians have a stable behavior over time, meaning they are occupying closer positions, for example, physician Msp 153 is kept in the first position during most of the time except in Q4 of 2013 when he/she moved to the second position. In other cases, a physician has an ascendant or descendant movement, which can indicate a change in the physician area or patients' behavior that might be interesting for the health insurance company.

### Table 2 – Temporal evolution by quartile of top 10 physicians with highest centrality measures in the physician-physician network, considering all states.

We noticed that there is a stable behavior in the position of the physicians over time, for example, the physician Msp 153 holds the first position in all quartiles except the fourth quartile of 2013 and remains in the second position (not getting far from the previous position). In this way, it is possible to measure these changes and thus know how much he/she is collaborating/influencing other physicians.

Another result obtained is that even having a high number of physicians (around 8k per quartile), the top 5 with the highest value in the eigenvalue metric in the second quartile of 2014,
besides their higher connections, they are also highly connected to each other, meaning that each one share patients with the other 5. When checking the specialty of each one we have an otorhinolaryngologist, a dermatologist, an endocrinologist, a hematologist, and a cardiologist. This fact, when analyzed in relation to the specialties that are connected, strongly suggest a collaboration between them in the care of the patient.

Discussion
According to Abdelzaher [13], patient sharing among physicians increases the likelihood of interaction and the sharing of information between them, as well as a chance to care for their patients in a synchronized way. Then, it can be concluded that the sharing of the patient between physicians strongly indicates that they form a care team. On the other hand, studies by Uddin [10] concluded that hospital physicians with high value in degree metrics indicate that they collaborate more with peers. Therefore, it is possible to conclude that physicians with high value in degree metrics collaborate and share information among each other, as well as interaction and synchronization of care to patients who are common to them. This all characterizes care coordination and thus they form a care team. Following the same reasoning, it is possible that physicians high values in degree metrics and eigenvalue, even not belonging to a hospital, possibly form a care team with their patients in common. This can be verified when analyzing the top 5 physicians who we studied, that demonstrate they are highly connected. According to Stukel et al. [18], providers tend to form informal care teams with physicians of different specialties only based on their share of patients and information. The high connectivity among the 5 top physicians suggests a sharing of patients and information and thus a formation of an informal care team.

In addition, his/her specialties (dermatologist, endocrinologist, cardiologist, otorhinolaryngologist, and hematologist) suggest the formation of a care team for chronic patients, since according to Stukel et al. [18], the chronic disease care is better when we have large multispecialty physician group practices. Such practices reduce complications and increase hospital and emergency readmission.

Beyond that, studies reported in Cunningham [9] assert that when we have cohesive and collaborative networks (of professionals or health institutions) it is beneficial to patient care and safety, so these informal care teams indicate that patient care and safety are probably good and should be supported and encouraged by providers.

The high-value metric indicates which physician has the most importance in this team, so the absence of him/her can damage the other relationships or even dissolve the care team. When analyzing the top 5 physicians the fact seems to make sense, because the most important physician is the cardiologist and the second is the endocrinologist. These specialties are usually present in the treatment of chronic diseases and thus this fact corroborates the analysis performed and the case studied.

From the Uddin’s research [10], doctors who have many connections (high value in the degree metric) suggest that they have more knowledge on how to assist their patients, since it makes it easier for the physician to share knowledge effectively with his or her other peers. In addition, it was found that the costs of hospitalization and readmission of patients are lower when the treatment is performed by highly connected physicians. Thus the physician with high values in the degree metric indicates that he/she belongs to several care teams and that he/she has a great amount of knowledge to care his/her patients, meaning better quality in the assistance and optimization in the use of resources.

Regarding the metric of betweenness, we can conclude that the greater the fluctuation is, the collaboration is less and the communication is impaired among the physicians [10]. Thus, we can define that finding this type of fluctuation between the members of a care team, probably, means that the treatment did not happen in a synchronized way and therefore is a candidate to have a higher health cost to the provider.

Finally, it is possible to analyze the relationship evolution of the physicians in the teams, when in this study we find the possibility to analyze the relationship of the medical community by quartile. This is important because in this way the provider can analyze the care teams and make decisions regarding the need for training, counseling, and meetings with all the stakeholders involved in order to improve the quality of the care service.

Conclusion
In this work it was possible to analyze the degree, eigenvalue and betweenness metrics that were very promising to define probable informal care teams by finding subsets of doctors with a high index of common patients. The high potential in calculating these metrics is verified in the members of the care team and from their results and from evaluating their performance. Another important point is to be able to evaluate over time the relationship evolution of these doctors in the team and with that take actions to improve the work of the team.

As future work, a more detailed analysis will be performed of a group of physicians highly connected in the graph ("informal care teams") and not highly connected. Analysis of what degree of connectivity is needed to know whether or not they actually form an informal care team will be carried out. Analysis of whether the cost of care of patients with the same diagnoses is lower than those with the same types of patients being taken care by physicians who are not highly connected will also be done. We can also analyze the impact the cost of patients being taken care by the set of doctors who have fluctuation in the betweenness (low communication and interaction among doctors) to see if there is any impact on the cost of treatment.

Measurement of Respiration Rate and Depth Through Difference in Temperature Between Skin Surface and Nostril by Using Thermal Image

Hieyong Jeonga, Yutaka Matsuura, and Yuko Ohno

*Department of Robotics & Design for Innovative Healthcare, Osaka University, Suita, Osaka, Japan, b Graduate School of Dentistry, Osaka University, Suita, Osaka, Japan, c Division of Health Sciences, Osaka University, Suita, Osaka, Japan.

Abstract

The purpose of the present study was to propose a method to measure a respiration rate (RR) and depth at once through difference in temperature between the skin surface and nostril by using a thermal image. Although there have been a lot of devices for contact RR monitoring, it was considered that the subjects could be inconvenienced by having the sensing device in contact with their body. Our algorithm enabled us to make a breathing periodic function (BPF) under the non-contact and non-invasive condition through temperature differences near the nostril during the breath. As a result, it was proved that our proposed method was able to classify differences in breathing pattern between normal, deep, and shallow breath ($P < 0.001$). These results lead us to conclude that the RR and depth is simultaneously measured by the proposed algorithm of BPF without any contact or invasive procedure.

Keywords:
Thermography; Respiratory Insufficiency; Respiratory Rate.

Introduction

Respiratory failure is one of the most common reasons for admission to the intensive care unit (ICU) and a common comorbidity in patients admitted for acute care [1]. What’s more, it’s the leading cause of death from pneumonia and chronic obstructive pulmonary disease (COPD) in the United States. Patients with impending respiratory failure typically develop shortness of breath and mental-status changes, which may present as anxiety, tachypnea, and decreased peripheral oxygen saturation ($SpO_2$) despite increasing amounts of supplemental oxygen [2], [3]. It is possible to assess the patient’s tissue oxygenation status regularly when the change of respiratory status is detected in the early stage. It follows that measuring the breath of the patient is important in the clinical environment.

The intensity of the care provided in the ICU requires many monitoring devices [4]. The ventilator, or respirator, is a breathing machine that helps patients breathe when they are too ill to breathe on their own. When signs and symptoms of respiratory failure are clearly strong, it is possible to use the ventilator at the appropriate time. However, when there are few signs and symptoms of respiratory failure, patients should be checked on a regular basis because symptoms can become suddenly or progressively worse. The current level of regular monitoring depends on the visual monitoring or stethoscope of caregivers, or the measurement of $SpO_2$ practically without any direct measurement of breath. In chronic respiratory failure, the only consistent clinical indicator is protracted shortness of breath [5]. The ideal respiratory monitor will not only detect respiratory failure regardless of the cause, but also indicate the cause. Respiratory failure, which leads to severe medical problems, remains an important issue. However there seems to have been little to preclude our simple method of detecting the early stages of respiratory failure in the clinical environment.

Different respiratory monitoring methods measure different physiological variables [5]. According to our literature review, it is possible to divide existing non-invasive respiratory monitoring methods into three categories: detection of movement, volume and tissue composition; airflow sensing; and monitoring of blood gas concentrations.

Detection of movement, volume and tissue composition

Muscle activity causes variations in thorax volume and pressure that give rise to variations in the venous return of blood to the heart. Variations in thorax pressure cause variations in air volume within the lungs, which in turn result in variations in transthoracic impedance [6]. The methods included in this category are, besides transthoracic impedance monitoring [7], measurement of chest or abdominal circumference, electromyography, various motion detectors and photoplethysmography [8]. However, this method still struggles with measuring while patients have any movement.

Airflow sensing

It is possible to detect airflow because expiratory air is warmer, has higher humidity and contains more $CO_2$ than inspiratory air. Variations in these parameters can be used for indicating the respiratory rate. Even sound caused by the airflow can be used in a similar fashion. To be able to measure tidal volume, the airflow must be measured and integrated over time, or the volume itself must be measured. Both methods need a facemask or mouthpiece to collect the air. They are used in spirometers [9], but are not commonly used in monitoring devices [10]. The airflow sensing method has difficulties in measuring under the normal circumstances of daily life.

Monitoring of blood gas concentrations

Respiratory activity can be assessed indirectly by monitoring $O_2$ and $CO_2$ concentration in arterial blood using non-invasive methods. Oxygen saturation is available by pulse oximetry, end-tidal concentration of $O_2$ or $CO_2$ can be measured in expiratory air, and transcutaneous blood gas concentrations can be measured through the skin. When the end-tidal concentration of $O_2$ or $CO_2$ is measured, the relative change in concentration between expired and inhaled air for oxygen is less specific (roughly 21% for inhaled air and 16% for exhaled air) than that
for CO2 (approximately 3% and nearly 0%, respectively) [3], [11], [12]. However, this method requires many contact points on the body of patient.

**Purpose**

From a present survey of the literature, it can be concluded that the need for effective respiratory monitoring is well known to the clinical engineering community. The number of papers in which new devices are demonstrated is large and, in fact, much larger than the number of publications devoted to the evaluation of such devices, indicating that the exploratory phase is still not finished [5]. Few solutions, if any, have been subjected to scrutinised evaluation on the basis of clinical usefulness. The reason for this may be that most monitoring devices are not yet adapted to clinical conditions. Monitoring respiratory activity in clinical practice introduces a number of problems that do not exist in a well-controlled laboratory-like situation. It must be possible to obtain the respiration status without disturbing or harming the patient. The monitoring devices should allow natural, unprovoked patient behaviour, such as turning to the side, moving head, arms and legs, and breathing through either nose or mouth [10]. Focusing on these reasons, the present study aims for caregivers to measure breathing patterns through the method related to airflow sensing under the non-invasive and non-contact conditions.

The main purpose of the present study was therefore to propose a method of measuring respiration rate (RR) and depth at once through differences in temperature between the skin surface and the nostril by using thermal imaging. Because our algorithm enabled us to make a breathing periodic function (BPF) under the non-contact condition during the breath, the peak-peak time and the distance between maximum and minimum peaks of BPF were helpful for measuring both the RR and depth at once.

**Materials and Methods**

**Materials**

**Human subjects and experimental procedure**

Three human subjects (Age: 29 ± 4 years old, Height: 171.4 ± 6.5 cm, Body mass index (BMI): 23.5 ± 3.2 kg/m²) were enrolled for the study at a local university. All of the subjects were informed of the nature of the experiments and consented for their data to be used in the study.

All thermal video recordings were carried out in parallel with a number of conventional contact-based respiration monitoring methods. This enabled a comparison to be carried out between the thermal imaging method and the conventional methods. The conventional contact respiration monitoring methods either measured the temperature variations between the inhaled and exhaled air using a nasal temperature probe, or measured SpO2. The thermal video recordings were performed with the subject resting comfortably in a chair. The recordings did not cause any form of distress to the subject. The recording room temperature was about 24°C and humidity was about 30%.

Fig. 1 shows an experimental procedure in the present study. It is considered that there are three types of breathing: normal, deep, and intentional shallow breathing. We would like to confirm whether the proposed method can measure the RR and depth at once or not, while it does not matter if the type of breathing pattern is changed. A subject performed the normal breathing during 30 s, and then did two times deep breathing within 1 min. Then the same performance was repeated one more time within an additional 1 min. Finally the subjects tried to perform the intentional shallow breathing during an additional 1 min, since for all subjects there were no problems with the experimental conditions. One subject performed three times under the same experimental conditions.

**Experimental system**

Fig. 2 shows an experimental system and environment. Apart from the 1.0 m distance, the thermal imager for the non-contact monitoring measures the ambient temperature of nostril and skin surface, and the nasal temperature probe for the contact monitoring also measures the ambient temperature around the nostril. The large monitor shows the respiration region of interest (ROI) which indicates the position of a rectangular boundary (blue rectangle) superimposed on a thermal image. A human pulse oximetry is used to measure blood oxygen saturation (SpO2) in the finger. A computer saves and analyzes all measured data with the calculation and analysis software of Matlab.

The Fluke thermal imager (Ti450 60 Hz) with MultiSharp™ Focus [13] delivers focus near and far in one image. Focus is one of the most important aspects of thermography, and an out of focus image can yield data that can lead to misdiagnosis. The Ti450 brings 640 × 480 SuperResolution can show us even more detail with 4x the pixel data. An accuracy of temperature measurement was ± 2% (at 25°C nominal, whichever is greater). The thermal imager could calculate each maximum, minimum and average value from the ROI automatically. The feature extracted from this ROI enabled the breathing signal to be produced. The thermal imager was fixed...
on a tripod in front of the subject at a distance of about one meter. Images were recorded at 9 frames per second (fps). The average respiration rate in an adult is about 15 cycles per minute (BPM), and the RR normally lies between 12 and 16 BPM at rest for an adult. Thus the RR in this paper is calculated as follows:

\[ RR = \frac{60}{\text{time gap}} \text{ [BPM]} \]

(3),

where the character of \( i \) represents the order of period of BPF.

Then, the distance gap between the maximum and minimum peaks indicates the depth of breathing. Thus the depth of breathing in this paper is calculated as follows:

\[ \text{Depth}_{(i)} = \begin{cases} \frac{\text{peak}_1 - \text{peak}_2}{\text{peak}_2 - \text{peak}_1}, & n = 1 \text{ if inhalation} \\ \frac{\text{peak}_2 - \text{peak}_1}{\text{peak}_1 - \text{peak}_2}, & n = 2 \text{ if exhalation} \end{cases} \]

(4),

where the character of \( i \) represents the order of period of BPF.

The maximum peak value of BPF indicates breathing. The breath corresponds to the phases of inhalation and exhalation. It is considered that differences in temperature between inhalation and exhalation indicates breathing. The number of peaks indicates the number of breaths, and the time gap between one peak and the next peak in the BPF indicates the RR. Generally the RR is measured in number of breaths per minute (BPM), and the RR normally lies between 12 and 16 BPM at rest for an adult. Thus the RR in this paper is calculated as follows:

\[ BPF(t) = T_{\text{max}}(t) - T_{\text{min}}(t) \text{ [°C]} \]

(2).

The maximum peak value of BPF indicates breathing. The breath corresponds to the phases of inhalation and exhalation. It is considered that differences in temperature between inhalation and exhalation indicates breathing. The number of peaks indicates the number of breaths, and the time gap between one peak and the next peak in the BPF indicates the RR. Generally the RR is measured in number of breaths per minute (BPM), and the RR normally lies between 12 and 16 BPM at rest for an adult. Thus the RR in this paper is calculated as follows:

\[ T_{\text{max}}(t) = \max(M_{BB(m,n)}) \text{ [°C]} \]

\[ T_{\text{min}}(t) = \min(M_{BB(m,n)}) \text{ [°C]} \]

(1),

where the character of \( m \) respresents rows of matrix \( M_{BB} \), and the character of \( n \) represents columns. It is observed that mainly the maximum temperature in the ROI indicates the skin surface, and the minimum temperature in the ROI indicates differences in the temperature around the nostril during breathing as shown in Fig. 3 (bottom). Although the maximum temperature of skin surface in the ROI does not show much change during breathing, the minimum temperature of the nostril shows significant change between inhalation and exhalation. Thus the breathing periodic function (BPF) of the proposed algorithm is derived as follows:

\[ \text{Depth}_{(i)} = \begin{cases} \frac{\text{peak}_1 - \text{peak}_2}{\text{peak}_2 - \text{peak}_1}, & n = 1 \text{ if inhalation} \\ \frac{\text{peak}_2 - \text{peak}_1}{\text{peak}_1 - \text{peak}_2}, & n = 2 \text{ if exhalation} \end{cases} \]

(4),

where the character of \( i \) represents the order of period of BPF.

The meaning in \( n = 1 \) indicates the depth of breathing during the inhalation, and the meaning in \( n = 2 \) indicates the depth...
large difference in BPF means the relative depth of breathing. For example, the difference indicates shallow breathing. Our proposed algorithm enables us to measure the RR and depth of breathing at once under the non-contact and non-invasive conditions by using the BPF of the thermal image as shown in equations (3) and (4). Furthermore, we would like to emphasize that it is possible to differentiate between inhalation and exhalation as shown in equation (4).

Results of measured BPF

It is necessary to understand the waveform of BPF which is used to measure the RR and depth of breathing. Figure 4 illustrates the results of measured BPF in comparison to measured data of the nasal temperature probe. The x axis indicates experimental time, and the y axis indicates temperature value. The black line represents the data of the nasal temperature probe, and the blue line represents those of BPF. The nasal temperature probe is regarded as the reference probe under the condition of shallow breathing as shown in Fig. 6. As the possible explanation, it was considered that the increasing slope of BPF for the nasal temperature probe under the condition of shallow breathing was smaller than those of other types of breathing (normal vs. deep: P < 0.001, deep vs. shallow: P < 0.001, normal vs. shallow: P = 0.164) except for the case (normal vs. shallow: P = 0.164 for the nasal temperature probe). As the possible explanation, it was considered that the increasing slope of BPF for the nasal temperature probe under the condition of shallow breathing as shown in Fig. 6 resulted in this problem. This may be why the weak inhalation under the condition of contact method resulted in the increasing slope of BPF due to the effect of skin surface temperature.

For the exhalation depth (Depth\(_{11}\)), although values of -3.86 ± 0.36°C, -4.59 ± 0.44°C, and -0.39 ± 0.14°C for the thermal under the condition of normal, deep, and shallow were different from those of -4.52 ± 0.41°C, -0.11 ± 0.24°C, and -0.39 ± 0.14°C for the probe under the same condition, it was easy to distinguish between the different types of temperature under the same condition, it was easy to distinguish between the different types of breathing under the natural conditions of daily life. In addition, because the BPF for measuring the RR and depth was based on differences in the temperature between the skin

proposed algorithm is discussed for clinical studies. We begin with. We thank Mr. Tianyi Wang, Mr. Takafumi Ohno, and Mr. Hideto Imai, and Prof. Michiko Kido, from Osaka Konoike Institute of Technology, Konoike Transport Co., Ltd. (Room K708, 7th Floor, 3-1, Ofuka-cho, Kita-ku, Osaka 530-0011, Japan), who helped us find this avenue of research to pursue.

Patterns can be easily spotted. The feasibility of this new algorithm, which measures the RR and depth of breathing through the BPF, is non-contact, non-invasive, and highly automated. This means that it can be safely employed to monitor patients in the clinical environment as well as at home for long periods of time.

The analysis of the experimental results indicates that the pattern of breathing is remarkably consistent for the same individual over time. Therefore, abnormalities in the individual patterns can be easily spotted. The feasibility of this new proposed algorithm is discussed for clinical studies.

Acknowledgements

This project was funded by the Hirose International Scholarship Foundation. We wish to thank the industrial partners involved with the Konoike Institute of Technology, Konoike Transport Co., Ltd. (Room K708, 7th Floor, 3-1, Ofuka-cho, Kita-ku, Osaka 530-0011, Japan), who helped us find this avenue of research to begin with. We thank Mr. Tianyi Wang, Mr. Takafumi Ohno, Mr. Hideo Imai, and Prof. Michiko Kido, from Osaka University for their analysis of the measured data and their generous comments on the analysis results.

Abstract

Systematic Reviews (SRs) of biomedical literature summarize evidence from high-quality studies to inform clinical decisions, but are time and labor intensive due to the large number of article collections. Article similarities established from textual features have been shown to assist in the identification of relevant articles, thus facilitating the article screening process efficiently. In this study, we visualized article similarities to extend its utilization in practical settings for SR researchers, aiming to promote human comprehension of article distributions and hidden patterns. To prompt an effective visualization in an interpretable, intuitive, and scalable way, we implemented a graph-based network visualization with three network sparsification approaches and a distance-based map projection via dimensionality reduction. We evaluated and compared three network sparsification approaches and the visualization types (article network vs. article map). We demonstrated the effectiveness in revealing article distribution and exhibiting clustering patterns of relevant articles with practical meanings for SRs.

Keywords:
Information Storage and Retrieval; Data Display.

Introduction

Research findings in the biomedical literature are used to guide and improve clinical practice. Systematic reviews (SRs) summarize evidence drawn from high-quality and up-to-date studies to inform clinical decisions and are considered the preferred source of Evidence-based Practice (EBP) [1]. However, the number of studies published each week is over 12,000, including more than 300 randomized trials [2].

During the SR process, researchers conduct an exhaustive literature search and appraise the best evidence to answer a clinical question. With the overwhelming volume of studies (aka. articles), the article screening process has become the most burdensome aspect and often causes information overload [3]. Typically, an exhaustive literature search would yield hundreds or thousands of articles. SR researchers need to spend weeks or even months screening articles to identify relevant ones for inclusion. In general, only 2% to 30% of searched articles are included for evidence synthesisization, which means researchers spend most of their efforts excluding irrelevant studies [4].

Existing studies have shown that automatic article classification with supervised machine learning (ML) is a valuable tool to facilitate the identification of relevant articles for SRs [4; 5]. However, such approaches have limited generalization to new SRs due to the dependency on prior supervised training data or manual annotations by domain experts. In our previous studies [6; 7], we demonstrated using established article similarities to assist in article screening for SRs in an unsupervised or semi-supervised manner. Article similarities were established in a feature space derived from several article elements i.e., title and abstract. Our approach achieved competitive performance in reducing SR workloads, and is highly generalizable [6]. Article similarities were also shown to capture article distribution (the structure of an article collection) and the clustering of relevant articles based on their strong similarities [7].

To extend the utilization of article similarities, we proposed to delve into the visualization of article similarities, and compared the effectiveness of different visualization approaches in revealing article distribution and clustering patterns. Under the notion of information visualization [8], articles are represented as visual elements, and their similarities are encoded by connections or visual channels. As pictures can provide more information with less clutter in less space [9], transforming an article collection into graphical representations can enable human’s insights into article distribution and clusters of similar articles. With the “visible article distribution”, SR researchers can identify studies of interest more efficiently. While there are many visualization approaches [8], we considered that an effective visualization should display articles along with their similarities in a human interpretable, attribute intuitive, and spatial scalable manner [10]. In this study, we focused on two types of visualization: graph-based network visualization (article network and distance-based (aka. geometry-based) map projection (article map). Other visualization types, such as adjacency matrix, hypergraph, and circular graph, were not included because of their limited structural analytics or spatial scalability.

For graph-based network visualization, we employed the node-link diagram with a force-directed layout to draw an article network, where articles are represented as nodes, and similarities are represented as weighted edges. Network visualization enables the exploration of graph topology and graph-based algorithms for advanced analytics [11]. However, an article network is almost a complete network due to the existence of non-zero similarities between most article pairs retrieved in an SR. Direct visualization of such a network is limited by human perception and important structural patterns are inaccessible, because of the extreme clutter presentation (“hairball”) [12]. To provide an effective network visualization, we implemented three network sparsification methods to reduce the network size via edge sampling [13; 14], expecting to preserve edges bearing important conceptual or structural information. The three network sparsification methods include 1) the established article similarity (AS) that predominantly retains edges for strong article similarities, 2) the derived algebraic distance (AD), first proposed by Chen 2011 [15] and used in John 2016 [13], values edges within neighborhoods and tends to preserve a network’s local structure, and 3)
the derived local degree (LD), first proposed by Lindner 2015 [14], values edges leading to hub nodes and tends to preserve the global structure. Both AD and LD have been shown to result in effective network sparsification [13; 14].

For distance-based map projection, we utilized the t-distributed Stochastic Neighbor Embedding (t-SNE) [16] to generate an article map with article features. The t-SNE technique converts the high-dimensional features into a matrix of pairwise similarities and visualizes it by projecting article points into a two-dimensional space, where article similarities are encoded as their spatial positions. t-SNE reveals local structures of the data and some important global structures such as clusters [16], though topological properties are not available in this map projection.

In summary, to effectively visualize article similarities, the purposes of the study are to 1) compare three network sparsification approaches, AS, AD, and LD; and 2) compare two types of visualization, graph-based network visualization (article network) and distance-based map projection (article map).

**Methods**

**Dataset**

We used publicly available data from 15 completed SRs [4; 17] produced by the Drug Effectiveness Review Project team (DERP). These SRs consist of article collections with coded decisions (inclusion or exclusion), which served as the gold standard to evaluate our performance. The size of these SRs ranges from 310 articles to 3465 articles (1249 articles on average), with the full-text level inclusion rate ranges from 0.55% to 27.04% (7.67% on average). We considered the full-text level included articles as relevant articles.

**Article Features**

Article similarities were established by article features. We generated (lexical) article features from several article elements, which were standardized by MEDLINE, including title (TI), abstract (AB), MeSH (MH), publication type (PT) and author (AU) [6]. We preprocessed the free-text of TI and AB by removing stop words, and stemming the remaining words with the classic Porter Stemmer. For MH, PT and AU, we used the exact strings as they were already standardly encoded. With the bag-of-words approach, we recorded the term frequency of each unigram word (TI and AB) and multi-word string (MH, PT and AU), and generated a feature vector for each article in the feature space. With article features, we calculated the article similarities to generate article networks. Alternatively, t-SNE calculated its own article similarities to generate article maps.

**Article Network**

An article network G(V, E) consists of a set of nodes (v \in V) representing articles and a set of weighted edges (e \in E) representing article similarities between corresponding endnodes. We calculated article similarities (Euclidean distances) from article features using Cosine similarity. The resulting similarity ranges from 0 to 1 for each article element. We used an equally weighted sum of the five element similarities as the final article similarity for the edge weight, ranging from 0 to 5.

**Network Sparsification**

An article network is almost a complete network due to the existence of non-zero similarities between most article pairs in an SR. Visualizing such a network is meaningless as it is referred to as a “hairball”. On average, the article networks of 15 DERP SRs have approximately 1,200,000 edges. Figure 1 illustrates an article network using an SR, Attention Deficit Hyperactivity Disorder (ADHD), which has 851 articles.

To overcome the limitation of visualizing an almost complete network, we implemented three network sparsification methods, AS, AD, and LD, with an expectation to reduce the number of edges, but preserve edges with conceptual or structural importance. The sparsification process consists of three steps: (1) network pre-pruning, (2) edge scoring, and (3) edge sampling.

**Step 1. Network pre-pruning.** In our experiments, we found that directly calculating AD or LD edge scores using neighborhood information in an almost complete network resulted in indiscriminate edge scores as most nodes share similar neighbors. Therefore, we initiated a relaxed pre-pruning step to keep the top neighbors (edges) based on edge weights for each node. We tested a series of pre-pruning parameters from 50% to 5%, and found that keeping the top 10% edges led to a better balance of avoiding the mass of trivial edges and retaining important edges. At this step, the edge number has been reduced to 176,492 on average. We then used this coarsely pruned 10% network as the baseline network. The 10% baseline network, although it sounds satisfying, is still insufficient because the pre-pruning only cuts off very trivial edges. As most SRs contain more than 3,000 articles (some are more than 10,000) and result in a quadratic number of edges, network sparsification is needed to retain the most important edges. Thus in the following steps we further aggressively reduced the number of edges.

**Step 2. Edge scoring.** With the baseline network, we calculated edge scores to further capture the edge importance from different perspectives using AS, AD, and LD.

**Article Similarity (AS)** To aggressively retain edges corresponding to strong article similarities, we directly used the established article similarities as edge scores. In other words, the edge weights were used as edge scores.

**Algebraic Distance (AD)** AD was proposed to preserve strong connections in terms of local structures [13; 15]. It generalizes the idea of estimating the Jaccard coefficient for neighborhoods through lazy random walks to determine the strength of connections of the edges. Specifically, nodes with similar neighbors are considered strongly connected. With the AD approach, these nodes converge to similar values via information propagation within the neighborhood and lead to high AD edge scores between them. Thus, edges with high AD scores represent strong local connections. Algorithm 1 shows the computation of AD. We ran multiple rounds (R=20) to obtain synthesized results.

**Algorithm 1 Computing algebraic distance (AD) [15]**

Input: Parameter \( \rho = 0.5 \), weighted adjacency Matrix (for weights \( w_{ij} \) and neighbors \( N_i \)), and randomly initialized vector \( x^{(0)} \) with \( |V| \) elements.

For \( k = 1, 2, \ldots, \) do

\[
\forall i \in V, x_i^{(k)} \leftarrow \rho x_i^{(k-1)} + (1 - \rho) \frac{\sum_{j \in N_i} w_{ij} x_j^{(k-1)}}{\sum_{j \in N_i} w_{ij}}
\]

\[\forall ij \in E, s_{ij}^{(k)} = |x_i^{(k)} - x_j^{(k)}|\]

End for

**Local Degree (LD)** LD was proposed to emphasize “hub” nodes, which are nodes with relatively high degrees [14]. The hub nodes and the connections to the hubs are important to present a network’s global structure. Because LD used the unweighted degree, in our study, we extended it to the weighted degree for our weighted article networks. For each node, we scored an incident (associated) edge based on the weighted degree of the other endnode. The LD approach assigns high scores to edges that lead to the hub nodes, and preserves the network “hub backbone”.

**Step 3. Edge sampling.** After the edge scores were calculated, we sampled the edges based on the edge scores. For each
node $v \in V$, we included the top $\deg(v)^3$ edges sorted by edge scores in descending order, where $\deg(v)$ is the degree of node $v$, and $e (0 \leq e \leq 1)$ controls the strength of sampling (filtering). We ensured that at least one incident edge was kept for each node. In this study, we used a sparsification parameter $e = 0.5$ to preserve at least $\deg(v)^3$ edges for each node.

**Force-directed Graph Drawing**

We used a force-directed algorithm to draw sparsified article networks in an aesthetically pleasing way in a two-dimensional space. As a spatial layout, it places nodes and edges by simulating a physical system. When the system comes to a mechanical equilibrium state, the pairwise geometric distance between the drawn nodes matches the graph theoretic pairwise distance. Specifically, similar article nodes tend to aggregate together while dissimilar article nodes are drawn apart. We implemented the algorithm in Gephi with the built-in Force Atlas layout [18].

**Article Map**

In an article map, articles are represented as a set of points and their similarities are explicitly encoded as spatial positions of article points. We used t-SNE [16] to generate article maps by providing t-SNE the established article feature vectors. t-SNE establishes article similarities (Euclidean distances) in the high-dimensional feature space, and creates an article map by projecting article similarities down to a two-dimensional space.

**t-SNE**

t-SNE [16] is a technique for visualizing similarity data by embedding high-dimensional data into a space of two or three dimensions. The resulting visualization is considered a map with data point distribution or a scatter plot. The t-SNE approach retains data structures by keeping similar data points close together while pushing dissimilar points far apart. It can also reveal important structures such as clustering.

As a non-linear algorithm for dimensionality reduction, t-SNE establishes high-dimensional Euclidean distances (similarities) between data points and converts them into a probability distribution. In the low-dimensional space, map points are placed as counterparts with a similar probability distribution. Gradient descent is used to minimize the divergence between the two distributions with respect to map points’ spatial positions. It is worth mentioning that the gradient of the cost function can be interpreted as physical forces between map points just like the force-directed graph drawing for networks. t-SNE has been shown to create higher-quality visualizations than linear methods (i.e. PCA and MDS) and other nonlinear methods (i.e. SNE and Isomap) [16]. We implemented t-SNE in MATLAB.

**Evaluation**

**Network Properties Evaluation**

We evaluated article networks based on the network properties in a network structure, including graph diameter, clustering coefficient, communities, and modularity. Graph diameter is the length of the shortest path between the most distanced nodes. A smaller diameter indicates a stronger concentration of a graph. Clustering coefficient measures the degree to which nodes tend to cluster together. Nodes with a higher clustering coefficient have higher transitivity in the neighborhood. Communities are subsets of nodes that are internally densely connected but externally sparsely connected. Modularity is designed to measure the strength of division of a network into communities. A high modularity corresponds to a better community structure. We used the Louvain method [19] for community detection which is proven to provide high-quality results. A graph’s community structure and modularity also reflect its local structure with respect to intra-community connections. In addition, a graph’s global structure can be reflected by the diameter, averaged clustering coefficient, and the number of communities. However, these topological properties were unavailable in article maps.

**Clustering Patterns Evaluation**

We evaluated the clustering patterns on both article networks and article maps. For article networks, we utilized communities detected by the Louvain method. For article maps, we applied $k$-means clustering to identify clusters based on the 2-dimensional map computed by t-SNE. For convenience, we used set to refer to community and cluster. We evaluated the clustering patterns of relevant articles that have been identified in the completed DERP SR reports (external criteria). Because of the highly-imbalanced dataset with only 0.55%-27.04% (7.67% on average) of relevant articles, we identified the set that contains at least 10% of relevant articles as dominant set. We examined the coverage (recall) and proportion (precision) of relevant articles in all dominant sets, and calculated the balanced F-measure ($F_1$ score). This was inspired by the classic measure of clustering quality that evaluates how well the clustering matches the gold standard classes, and interprets the clustering as a series of decisions. Other measures such as the purity, normalized mutual information, and Rand index, are not suitable for the highly-imbalanced dataset.

**Results**

**Network Properties**

We reported the network properties of the baseline network and the sparsified networks with the averaged results of the 15 DERP reports (Table 1). Because edge sampling was implemented based on individual nodes, the number of edges after the sampling was not the same when using different sparsification methods. The clustering coefficient was also the average of all article nodes for each SR.

</table>

As shown in Table 1, the number of edges was significantly reduced from 176,492 to approximately 13,000 after sparsification. All sparsification methods resulted in increased diameters and decreased clustering coefficients because of the removal of most edges. However, they also showed differences. AS brought the highest modularity with a larger number of communities, but altered the baseline graph diameter and clustering coefficient to a greater extent. Similarly, AD altered the baseline diameter and clustering coefficient, but provided a slight gain in modularity. LD retained a similar graph diameter, clustering coefficient, modularity, and community number compared to the baseline. In summary, AS resulted in a better community structure; AD tended to retain the baseline local structure (with slightly higher modularity); LD performed the best in preserving the baseline global structure.

**Clustering Patterns**

We examined the clustering patterns of relevant articles in article networks and article maps. The optimized number of communities in an article network was determined by the Louvain method (default resolution setting). For the $k$-means clustering in an article map, we applied the knee (elbow)
method to identify a proper value range for the number of clusters, k. We found the resulting range approximately aligned to the number of communities detected by the Louvain method in AS networks. Thus for each SR, we had k equal to the number of communities in the corresponding AS network. In Table 2, we reported the total number of sets (communities or clusters), the number of relevant sets that contain at least one relevant article, and the number of dominant sets that contain at least 10% of relevant articles. We also reported the overall size of all dominant sets by calculating the ratio of articles contained by the dominant sets. We calculated the corresponding recall, precision, and F1 score regarding the relevant articles in all dominant sets. Again, all the results were averaged from the 15 DERP SR reports.

<tr>
<td>F1 Score</td>
<td>0.1823</td>
</tr>
</tbody>
</table>

As shown in Table 2, the AS network and article map generated by t-SNE had the largest number of sets (10) and relevant sets (6 and 8), but the number of dominant sets was only 3. Their dominant sets covered 83.16% and 76.45% of relevant articles with a size of 35.13% and 31.36% of entire articles. Both of them had lower recalls but the highest precisions and F1 scores (0.2623 and 0.2618). They achieved a good quality of clustering relevant articles by decomposing articles into finely separated sets. The LD network behaved similarly to the baseline network, with the relevant articles spreading into coarsely divided sets. With the highest recalls, 3 out of 5 sets acted as dominant sets and covered over 90% of relevant articles. However, their precisions and F1 scores (0.1713 and 0.1823) were lower than others because the conservative discrimination. The AD network brought moderate performance in recall, precision, and F1 (0.1983). Specifically, 90.14% of relevant articles were covered by dominant sets, with a size of 56.35%.

In summary, network sparsification led to a more recognizable network structure by concentrating nodes towards hubs and forming bridges among hubs. Figure 3 shows an article map generated by t-SNE. We observed the clustering patterns of relevant articles (green points).

In Figure 4, we illustrated communities in the AS network and clusters in the article map. Article nodes (points) were colored by communities (clusters). Dominant sets of relevant articles were marked by green rectangles, which further demonstrated the effective clustering of relevant articles.

Discussion

Sparsification Schemes: AD and LD were applied to sparser networks (i.e. social networks and citation networks) in early works [13; 14]. To our knowledge, we were the first to apply AD and LD to article network sparsification. Due to the densely-connected nature of article networks, a relaxed pruning step was used. In this study, we found that AD retained the local network structure, LD preserved the global network structure (also supported by other works [13; 14]), and AS performed the best in revealing the community structure. In addition, considering the clustering of relevant articles, AD and LD had lower precisions, but higher recalls, resulting from their integration of the network structure; while AS had a lower recall, but a higher precision because it aggressively concentrated relevant articles. Another encouraging finding was that by keeping only 1-3% of edges (13,000 edges on average) from the original networks (1,200,000 edges on average), we can reveal meaningful network structures and important clustering patterns.

Article Network vs. Article Map: Article networks sparsified by AS and articles maps generated by t-SNE achieved similar results in revealing article distribution and clustering patterns. Both of them aggregated the majority of relevant articles into finely separated set(s). While the AS network had a slightly lower precision than the article map, it had a higher recall which is important for SRs. For article networks, a sparsification process is needed to eliminate clutter presents; but we were able to explore graph topology and apply graph-based algorithms for advanced visual analytics, such as community detection and graph traversal. Article maps are created by t-SNE or other dimensionality reduction algorithms that can handle the crowded article feature space; but topological analysis is not available. The same article feature generation step was applied to the network visualization and the map projection process. Future investigation could include a user study to gather feedback regarding the selection of visualization approaches for SRs.

Illustration of Visualization

We illustrated the above mentioned results with visualization using an SR report, ADHD, as an example. The ADHD report has a total of 851 articles: 20 were included at the full-text level (relevant articles), 64 were only included at the title/abstract level, and 767 were excluded at the title/abstract level.

Figure 2 shows article networks before and after sparsification. The baseline network had clutter presents that limited human perception without explicit structures. All sparsified networks provided more interpretable structures and revealed the clustering of relevant articles (green nodes). Specifically, AS provided the most manifest community structure with meticulous separations, where relevant articles were highly concentrated. AD retained local connections and led to densely connected neighborhoods. LD preserved the hub backbone structure by concentrating nodes towards hubs and forming bridges among hubs.
Conclusions

We visualized article similarities with sparsified article networks and article maps. We demonstrated the effectiveness in revealing meaningful article structures, and exhibiting clustering of relevant articles in an intuitive and human interpretable manner. Effective visualization of article similarities has practical meanings to facilitate article screening for SR researchers.

A Hybrid Method for ICD-10 Auto-Coding of Chinese Diagnoses

Abstract
The Chinese Version of Classification and Codes of Diseases (CCD) is an expanded version of ICD-10. Hospitals are required to assign CCD codes to discharge diagnoses in China. To handle the contradiction between a shortage of skilled CCD coders and increasing coding efficiency, a CCD auto-coding method is urgently needed. In this study a hybrid auto-coding method was proposed based on the lexical characteristics obtained through the analysis of a corpus of 1537 diagnoses with normative CCD code. It combines the rule-based approach, the Chinese characters-based distributed semantic similarity and the dictionary-based approach. The rule-based approach was proved to be efficient and precise at the cost of time and manpower. The semantic similarity approach shows poor performance. The old-fashioned dictionary-based approach ends in leading significance. The final accuracy of this hybrid approach is 96.9% in the test.

International Classification of Diseases; Clinical Coding; China

Introduction
The International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) [1] was defined as a system of categories to which morbid entities are assigned according to established criteria. The ICD was used to translate diagnoses of diseases and other health issues from linguistic words into alphanumeric codes, which permits easy storage and retrieval, and systematic recording analysis of mortality and morbidity data. The classification consists of 22 chapters, which were divided into homogeneous blocks of categories, which are further subdivided to at most 10 subcategories each.

The Chinese Version of Classification and Codes of Diseases (GB/T 14396-2001) [2], short for CCD, is an expanded version of ICD-10 and is widely used in China. It has a strict and organized classification hierarchy expanded from four-char ICD-10 (9505 subcategory) to six-char codes (23106 expansion) that allows one-to-one mapping from diseases to codes to support the management, inquiry, search and statistical analysis of data.

In 2011, the National Health and Family Planning Commission of the People’s Republic of China promulgated the notice on using CCD codes for encoding discharge diagnoses in the summary page of medical records after January 1, 2012 [3].

Accurate CCD diagnosis coding is critical to patient care, billing purposes, and research endeavors [4]. Correct, standard and complete hospitalization diagnosis by doctors and careful implementation of coding principle and careful reading about medical record content are the guarantee of ensuring correct coding [5]. The patient’s course of disease is defined as a procedure from admission to discharge with a narrative discharge summary including the primary and secondary diagnoses by manual input. The paper trail is defined as a creation of medical record from the recording of the admitting diagnosis to the assignment of the ICD codes after discharge [6][6].

Errors such as “upcoding” and misspecification may be introduced during the coding by the lacking of medical knowledge and coder’s experience, attention, and persistence, the ability to interpret the diagnoses and the inconsistency between CCD phraseology and clinical phraseology, such as the synonyms and abbreviations used to describe the same condition. [6].

In most of large hospitals, several professional coders are hired by the medical record department to supplement the CCD codes in the summary page of hospital records [7]. Nevertheless, the contradiction between a shortage of skilled coders and an excess of hospital patients makes it a tough task to encode both the primary and the secondary discharge diagnoses with ICD-10. In a first-class hospital in China only two coders are hired to assign CCD codes for about 2000 inpatients everyday.

Physicians in the same department usually follow the same naming convention so that there is little difference in the record names of the same disease in its summary page of hospital records. Similar grammar mistakes and medical language process makes it feasible to analyze the underlying rules of encoding diagnoses into CCD codes and develop a CCD auto-coding tool for physicians.

To reduce the workload of human coders, Medori and Fairon [8] extracted necessary information from French discharge summaries and combined the symbolic approach and statistical approach, since a large corpus of clinical notes was available. Subotin and Davis [9] developed a system for predicting ICD-10-PCS codes from the English clinical narrative using partial hierarchical classification and confidence calculation and estimation. In China, Ning and Yu [10] proposed an algorithm to implement ICD-10 coding automatically for clinical diagnoses in Chinese and calculated the semantic similarity between terms by the definition of distributed semantic similarity. Considering the linguistic features of Chinese, the results indicate that term vectors constructed from words have a higher precision than that from Chinese characters.

In this paper, we analyze and summarize the characteristics of discharge diagnoses written by doctors in the Nephrology Department, Dayi Hospital. A rule-based data pre-processing method and a computer-assisted CCD coding method are proposed.
Methods

In this study, we collected a corpus, analyzed the lexical characteristics of Chinese diagnoses and proposed three approaches to auto-code CCD.

Corpus Collection

The corpus of patient Electronic Medical Record (EMR) summary pages were collected from a Clinical Data Repository (CDR) [11] system, which was implemented in the 2000 beded hospital in China. The summary page was in XML format and each summary page recorded one primary discharge diagnosis of the patient and its associated CCD code assigned by human coders. A corpus of 1537 diagnoses with CCD codes considered as the gold standard was randomly selected and parsed from data repository as the typical language samples to analyze the lexical characteristics.

Lexical Characteristics Analysis

Due to individual language habit, doctors may use diverse names to define the primary diagnoses and describe the status of disease [6]. ICTCLAS [12], which is a Chinese lexical analyzer, is used to tokenize the long disease names into minimal semantic units (Table 1).

The analysis results include the tokenization result and observational conclusions (Table 2). The hand-input phrases usually consist of three components: multiple attributes, one core noun and punctuations. The punctuations consist of redundance such as bracket and digit symbols. Several common wrongly written characters of discharge diagnoses are discriminated and the reason is analysed.

Computer-assisted Coding Method

We proposed three approaches for automated CCD code assignment: the rule-based approach, the Chinese characters-based distributed semantic similarity approach and dictionary-based approach.

Rule-based auto-coding

The rule-based approach contains nine irregular naming patterns established from practice and experience (Table 3). Superfluous prefix or suffix are omitted. Typical prefix words include anatomopic parts (eg. ”legate” Chinese for “leg”), nouns of locality (eg. “左” Chinese for “left”) and scope (eg. “多发” Chinese for “multiple”), words end with particular Chinese characters (eg. 性 property).

</table>
Conjunctions (e.g. “合并” Chinese for “accompanied”) and meaningful punctuations (e.g. “逗号” Chinese for “comma”) are sometimes used to connect two individual disease names. The CCD dictionary may exclude the combination but include the individual.

Each permutation of the rules applied to one original diagnosis name will generate a candidate. The candidates that can be matched to any disease name in CCD dictionary or custom dictionary (much more on this later) completely will be selected. The standard disease name will also be processed if it contains particular characters or symbols. The rule-based auto-coding is invalid if it’s not an exact match. The candidate with a perfect match and maximum character count will be recommended as the paired CCD code.

**Chinese characters-based distributed semantic similarity**

The Chinese characters-based distributed semantic similarity [10] is a method which can implement ICD-10 coding automatically for clinical diagnoses in Chinese and has a high precision in the test set. It is measured by the cosine similarity between vectors converted from Chinese characters.

\[ \hat{p} = (p_1, p_2, \ldots, p_m) \] and \( \hat{q} = (q_1, q_2, \ldots, q_n) \) are defined as the standard CCD name (the count of Chinese characters is \( m \)) and the hand-input name (the count is \( n \)) respectively.

\[ p^T_i = (p_{i1}, p_{i2}, \ldots, p_{im}), q^T_i = (q_{i1}, q_{i2}, \ldots, q_{in}) \] are the vectors extracted from \( p^T \) and \( q^T \) where \( p_{ik} = q_{ik} (k \in [1, K]), p^T_i = q^T_i, p_i \in [p_1, p_2, \ldots, p_m], q_i \in [q_1, q_2, \ldots, q_n]. \) The similarity score is

\[ \text{sim}(p, q) = \frac{K}{M} \frac{K}{N} \left[ \vec{I} \cdot \vec{J} \right] \]

where

\[ \vec{I} = (i_1, i_2, \ldots, i_K), i_k \in [1, M] \]

\[ \vec{J} = (j_1, j_2, \ldots, j_K), j_k \in [1, N] \]

and \( M \) is the count of Chinese characters of the standard CCD name, \( N \) is the count of Chinese characters of the hand-input name, \( K \) is the count of common characters.

For example, there are one original disease name 巨幼细胞贫血(megaloblastic anaemia) and three candidates of CCD name 巨幼红细胞贫血(megaloblastic anaemia), 巨幼细胞贫血(megaloblastic hereditary anaemia), 营养性巨幼细胞贫血(nutritional megaloblastic anaemia). We have

\[ \hat{q} = (巨, 幼, 细, 胞, 贫, 血), N = 6 \]

\[ p^T_1 = (巨, 幼, 红, 细, 胞, 贫, 血), M_1 = 8 \]

\[ p^T_2 = (巨, 幼, 细, 胞, 贫, 血, 传, 性, 贫, 血), M_2 = 9 \]

\[ p^T_3 = (营, 养, 性, 巨, 幼, 细, 胞, 贫, 血), M_3 = 10 \]

The extracted vectors are \( p^T_1 = p^T_2 = p^T_3 = q^T = (巨, 幼, 细, 胞, 贫, 血), K = 6, \) where the sequence vectors and similarity scores are

\[ \vec{I} = (1, 2, 3, 4, 5, 6) \]

\[ \vec{I}_1 = (1, 2, 4, 5, 7, 8), \] \( \text{sim}(p_1, q) = 2.37 \)

\[ \vec{I}_2 = (1, 2, 3, 4, 8, 9), \] \( \text{sim}(p_2, q) = 2.83 \)

\[ \vec{I}_3 = (4, 5, 6, 7, 9, 10), \] \( \text{sim}(p_3, q) = 4.95 \)

The non-Chinese characters are removed before similarity calculation. The candidate code with the lowest similarity score will be assigned to the disease name. In the above example, the CCD code of \( p_1 \) should be assigned to \( q \).

**Dictionary-based approach**

The dictionary-based approach is to construct a custom dictionary which extended the CCD standard disease name with disease names used by doctors and its corresponding CCD codes given by human coders. The scope of the dictionary tends to expand over time. The term absent from CCD dictionary will be assigned to its newly assigned CCD code when it appears again.

The three approaches are integrated to follow the priority order: custom dictionary > rule-based auto-coding > Chinese characters-based distributed semantic similarity. If the original diagnosis fails to match any CCD of the standard CCD dictionary or the custom CCD, it is then processed by the rules. This procedure may generate several candidates. If no candidate is obtained, the auto-coding fails. Otherwise the candidates are compared with CCD of the standard CCD dictionary or the custom CCD. If no candidate matches successfully, the CCD code with a highest score of Chinese characters-based distributed semantic similarity is selected as the final result. In a situation where there are multiple matches in standard or extended CCD dictionary, the first candidate in the default sort is selected as the final match. The flow diagram of the hybrid method is shown in Figure 1.

</table>

Chinese characters-based distributed semantic similarity method was a method dedicated to Chinese characters with mediocre accuracy, poor efficiency and small influence. Only 1.2% discharge diagnoses were under valuable influence.

The dictionary-based approach improved the matching rate from 52.9% to 97%. It proved to be an invalid approach initially and would play a leading role as it scaled. It may start out as unreliable, but it can be trained and developed into a practical handbook coders can rely on. At present, most of the hospitals seldom established this kind of dictionary and even had no information system assisting the human coders [13].

For mismatched cases, some errors are analyzed. One case is that the original name is 双下肢动脉硬化伴多发斑块形成 (the hardening of the arteries of both lower limbs with multiple plaque buildup) and the standard name is 下肢动脉粥样硬化 (atherosclerosis of arteries of lower limbs). Another case is that the original name is 系统性小血管炎肾损害 (kidney damage due to (not mentioned in Chinese) systemic small-vessel vasculitis) and the standard names are 系统性血管炎 (systemic small-vessel vasculitis) and 系统性结缔组织疾病引起的肾小球疾病 (glomerular disorders in systemic connective tissue disorders, ICD-10: N08.5*). It infers that mismatches may be caused by the usage of totally different syntax.

Discussion

The combination of the three approaches reached 96.9% precision for the auto-coding of 6-char CCD in the Nephrology Department. Ning et al. [14] used a hierarchical method to automatically encode Chinese diagnoses through semantic similarity estimation, reaching the precision of 4-char coding is about 92%. It indicates that our method improved the fineness without diminution of accuracy.

The rule-based method and the dictionary-based approach cost running times within 1 second, while the Chinese characters-based distributed semantic similarity is long-running process. The average running time of the method proposed by Ning [14] is about 1 second. For the little sense made by the Chinese characters-based distributed semantic similarity method, it is suggested to be abandoned.

The rule-based method in this paper is essentially an extended dictionary matching approach enriched with rule preprocessing. It is not a traditional rule based approach for other tasks. A hospital-wide, highly efficient, precise auto-coding system coordinating the rule-based method and the dictionary-based approach is the next challenging task in our project.

The rule-based method and dictionary-based approach take merely a fraction of operation time. However, the Chinese characters-based distributed semantic similarity method requires more internal storage and longer execution time, because the dictionary is large and the similarity calculation and comparison between each code are time-consuming.

Conclusion

In this paper we introduced the usage condition of ICD-10 in China and the expanded version of ICD-10 known as CCD. The existing approaches assisting human coders to assign CCD codes to diagnoses context were reviewed. Three methods were proposed. Rule-based auto-coding method is of high effectiveness and precision. Chinese characters-based distributed semantic similarity method performed poorly. The dictionary-based approach proved to be gradually crucial and reliable.

However, there are still limitations. The hybrid approach is of low portability and interoperability, because rules for auto-coding and the custom dictionary differ from hospital to hospital. Rule-making and dictionary construction for each single hospital is of high cost and low efficiency. In future work, we will conduct the in-depth analysis of auto-coding and develop a hospital-wide system to assist the work of human coders.

Abstract

Phenotyping is an automated technique for identifying patients diagnosed with a particular disease based on electronic health records (EHRs). To evaluate phenotyping algorithms, which should be reproducible, the annotation of EHRs as a gold standard is critical. However, we have found that the different types of EHRs cannot be definitively annotated into CASEs or CONTROLS. The influence of such “possible patients” on phenotyping algorithms is unknown. To assess these issues, for four chronic diseases, we annotated EHRs by using information not directly referring to the diseases and developed two types of phenotyping algorithms for each disease. We confirmed that each disease included different types of possible patients. The performance of phenotyping algorithms differed depending on whether possible patients were considered as CASEs, and this was independent of the type of algorithms. Our results indicate that researchers must share annotation criteria for classifying the possible patients to reproduce phenotyping algorithms.

Clinical Phenotyping, Data Annotation, Electronic Health Records

Introduction

Background and problems

To improve healthcare quality and clinical research, it is critical to identify patients diagnosed with a particular disease. As structured data on diagnoses in electronic health records (EHRs) are limited in terms of accuracy and completeness [1, 2], the demand for automated techniques for identifying patients diagnosed with a particular disease based on EHRs, so-called phenotyping, has been increasing [3, 4]. In previous studies, we applied published algorithms to EHR datasets of Japanese patients [5, 6], which required annotated EHRs as a gold standard to evaluate the algorithms. Among the several annotation techniques, we chose manual annotation because it is more accurate than others, and over 75% of previous studies employed it [4]. Through the annotation process, we found that it is often difficult to annotate EHRs as definite CASE or CONTROL patients as a gold standard [6].

Annotation criteria are critical for phenotyping algorithms because they directly affect the calculation of the algorithms’ performance. If researchers do not share how to annotate such “possible patients,” the published performance of a phenotyping algorithm would differ among research teams because the CASEs would differ, even if each dataset had identical characteristics (Figure 1).

Introduction

Background and problems

To improve healthcare quality and clinical research, it is critical to identify patients diagnosed with a particular disease. As structured data on diagnoses in electronic health records (EHRs) are limited in terms of accuracy and completeness [1, 2], the demand for automated techniques for identifying patients diagnosed with a particular disease based on EHRs, so-called phenotyping, has been increasing [3, 4]. In previous studies, we applied published algorithms to EHR datasets of Japanese patients [5, 6], which required annotated EHRs as a gold standard to evaluate the algorithms. Among the several annotation techniques, we chose manual annotation because it is more accurate than others, and over 75% of previous studies employed it [4]. Through the annotation process, we found that it is often difficult to annotate EHRs as definite CASE or CONTROL patients as a gold standard [6].

Annotation criteria are critical for phenotyping algorithms because they directly affect the calculation of the algorithms’ performance. If researchers do not share how to annotate such “possible patients,” the published performance of a phenotyping algorithm would differ among research teams because the CASEs would differ, even if each dataset had identical characteristics (Figure 1).

Why is the annotation of possible patients indefinite?

In EHR annotation for type 2 diabetes mellitus (T2DM), we identified three types of EHR data in terms of possible patients [6]. Each of these suggests a different likelihood of T2DM, as shown in the following examples:

Example 1: Antiglutamic acid decarboxylase (GAD) antibody ≥ 1.6 U/mL and antiislet antigen 2 (IA2) antibody ≥ 0.4 U/mL

Example 2: “...T2DM is likely...”

Example 3: “...He met the diagnostic criteria for DM... Type 1 DM is unlikely because... Secondary DM is denied...”

In example 1, the explicit information about the disease name, such as the direct noting of “type 1 DM,” is not provided, but the information implies a low possibility of T2DM; that is, the high value of the anti-GAD antibody or anti-IA2 antibody suggests type 1 DM. Example 2 includes an explicit but indefinite description (“likely”), and the annotation result may differ among annotators. Example 3 provides no direct information about the type of DM, but the contextual information can increase the conviction that the patient has T2DM; that is, it denies other types of DM. These ambiguous descriptions are sufficient for medical experts who have medical knowledge, and they sometimes dare to describe EHRs ambiguously to accurately record the facts when they cannot diagnose patients with certainty [7]. However, these descriptions are not necessarily sufficient for researchers who sometimes expect the definite truth. This is one of the essential limitations of retrospective EHR-based studies across institutions or countries. Moreover, the fact that each patient’s EHRs contain many such ambiguous descriptions makes reproducible annotation difficult.

As surveyed, one study separated definite and possible CASEs to identify rheumatoid arthritis and grouped possible CASEs with CONTROLS [8]. For other diseases, such as multiple sclerosis, the possible patients were identified for multiclass classifications [9–11]. However, they have not shown multiple types of possible patients, and the published annotation criteria were disease dependent. For other diseases, even the existence of possible patients as a gold standard has not been examined. No studies have shown whether the performance of a
phenotyping algorithm will be influenced by which types of possible patients are classified as CASEs. We aim to quantitatively clarify these issues and mitigate the ambiguities to facilitate reproducible phenotyping algorithms [12].

Research objective, novelty, and related work

We analyze EHR data to examine the impacts of the annotation criteria for classifying possible patients on (1) the proportion and characteristics of CASE patients and (2) the performance of phenotyping algorithms. To accomplish this, we create a nonbinary annotation method based on the conviction of a target disease. Our targets are four chronic diseases. This study’s originality is to handle directly the uncertainties in records of diseases and their influences on the algorithms’ performance using real world data. One study simulated the loss of power of phenotyping algorithms due to bias in the EHR data [13], but did not mention the information bias related to the annotation criteria. No phenotyping studies have addressed the uncertainties in disease records [7].

Methods

Target diseases, eligible subjects, and EHR data

Our targets are four diseases from the Unified Medical Language System (UMLS) Metathesaurus—common diseases: (i) T2DM and (ii) essential hypertension (HT); and rare diseases: (iii) primary biliary cirrhosis (PBC; the full disease name is changed since approximately 2015 [14], but this study used data until 2014) and (iv) autoimmune hemolytic anemia (AIHA). We selected chronic diseases, which have associated clinical guidelines in Japan [15–18], to focus only on the presence of diseases. A disease must be diagnosed through a combination of several tests. If a disease can be diagnosed using one test, it does not require a phenotyping algorithm. This study involved 650 patients (mean age 52.6; 57.2% female) randomly selected out of 104,522 patients who made at least two visits to the University of Tokyo Hospital between 1/1/2009 and 12/31/2014 and at least one visit in 2012. We used the EHR data over six years (2009–2014).

Detailed annotation (DA) method

In this study, annotators checked EHR data retrospectively and determined a “CASE” based on the degree of conviction that the patient had a target disease, which was recorded in EHRs by clinicians who examined the patient. The examples of EHRs in the Introduction section suggest that possible patients should be annotated into several types and that annotation should be independent of the data structure. Labelling the information itself would be useful for reproducible annotation of any EHRs because the annotation results would differ among research teams using different information. We divided the information in the EHRs into two axes, namely explicit information and context (Figure 2); moreover, along each of the two axes, we classified the elements affecting multilevel degree of conviction of a target disease. We have called this the detailed annotation (DA) method (Table 1).

![Figure 2– Annotation axes: explicit information and context.](image-url)

Explicit information includes definite (Table 1(a), (d)) and possible ((b), (c)) descriptions of disease names, and meeting the diagnostic criteria ((c), (e)), which means that annotators can retrospectively determine that the patient met the diagnostic criteria. The description “T2DM is likely” is an explicit, possible description of the target disease (T2DM) and belongs to explicit information (b). Contexts include the EHR data implying a target disease (α); upper diseases (β); and the absence (γ), (δ) and presence (ε) of differential diagnoses and sibling diseases; and possible (δ) and definite (ε) descriptions of diseases which are treated by the same medication used for the target disease. For T2DM, the description “Type 1 DM is unlikely” belongs to context (α) because T1DM is a sibling disease of T2DM; this description implies T2DM. The pair of the structured data of the high values of the anti-GAD antibody and anti-IA2 antibody belongs to context (ε) because they suggest T1DM. For essential HT, the narrative and definite descriptions that the patient is medicated with an antihypertensive drug not for HT but for angina belongs to (ε); this description implies weak conviction that the patient has essential HT.

The combination of each element of each of the two axes leads to the seven categories of disease conviction, from a definite CASE (category (1)) to a definite CONTROL (category (7)). As an intermediate concept, category (4) indicates the upper disease. A patient with explicit information (b) and context (α) is classified into DA category (2). Patients in the categories (2)–(6) are possible patients.

Experimental setups

Two clinicians (authors) each annotated the EHRs of all 650 patients for each of the four diseases based on the DA categories. The annotators discussed and made final decisions for mismatches. We used Fisher’s exact test and Fisher’s pairwise exact test (Bonferroni correction) to compare the proportion of possible patients among the diseases. To analyze the patients’ characteristics according to the DA categories, we performed statistical analyses of the null hypothesis that the averages of the maximum value of each lab test of each patient or the proportions of each element used in the guideline-based phenotyping algorithms (described later) would be equal among the categories. For continuous data, the variances of each category were found to be unequal by a Bartlett test; the nonparametric Kruskal–Wallis test and the Mann–Whitney U test (Bonferroni correction) for pairwise comparison were performed. For categorical data, we used Fisher’s exact tests and Fisher’s pairwise exact test (Bonferroni correction). The threshold for significance was \( p < 0.05 \). We used R-3.1.3, the coin package 1.1-2, and the fmsb package 0.5.2.

To assess the impact of the annotation criteria on the performance of phenotyping algorithms, authors developed rule-based phenotyping algorithms for each disease (Table 2) using data that are referred in each guideline [15–18] and are stored according to HL7 2.5 (ISO 27931:2009). We call these guideline-based (GB) algorithms. For each algorithm, we changed the annotation criteria by altering the threshold of the DA category in which patients are considered as CASEs from the category (1) to (6), and calculated the values of the evaluation metrics at each threshold. The DA category (7) was excluded from the threshold because it was an unrealistic assumption for all patients (the categories (1)–(7)) to be CASEs. The evaluation metrics are as follows: recall is True Positive (TP)/TP + False Negative (FN), precision was TP/(TP + False Positive (FP)), specificity was True Negative (TN)/TN + FP), and negative predictive value (NPV) was TN/(TN + FN). To examine whether the impact of the annotation criteria depended on a particular phenotyping algorithm, we performed the same experiment for the other phenotyping algorithms, which used only one billing code for each disease. We call these naïve algorithms. More detailed explanations of the DA method and phenotyping algorithms are presented on GitHub.1
Table 1– The DA method. Degrees of disease conviction are classified into categories (1)–(7) indicating certainty, probability, possibility, upper disease, the possibility of other diseases, the probability of other diseases, and definite other diseases respectively.

Table 2– GB phenotyping algorithms developed in this study.

(i) T2DM: Patients with (A) AND ((B) OR (C)), modified [19]
(A) Excluding other types of DM
(B) Antidiabetic medication
(C) T2DM billing codes AND abnormal lab test more than two times.

(ii) Essential HT: Patients with (A) AND (B)
(A) Excluding secondary HT
(B) HT billing codes except (A) OR medication of ARB/ACE inhibitor

(iii) PBC: Patients with (A) AND (B)
(A) Anti mitochondrial antibody (AMA) is positive
(B) (GTP = 68 IU/L AND ALP = 359 IU/L) OR PBC billing codes

(iv) AIHA: Patients with (A) AND (B) OR (C))
(A) More than four abnormal lab tests, which means hemolytic anemia
(B) Direct Coombs test is positive AND (AIHA billing codes OR no billing codes for other diseases that cause anemia
(C) Disease names of AIHA in EHR, applying the technique in [20]

Figure 3– The numbers and distributions of patients classified into each DA category differ among the diseases.

Figure 4– Changes in the performance of GB algorithms depending on the threshold of CASEs among the diseases.

Results

Figure 3 shows the annotation results based on the DA categories (weighted $k$ statistics $= 1.00$ for each disease). The mismatches between the annotations of two patients was caused by an oversight of the EHRs and those of seven patients were caused by misunderstanding of the contexts. The category (7) included more than 500 patients for each of the four diseases and is excluded from Figure 3. All four diseases included possible patients classified into DA categories (2)–(6). The distributions of patients differed among the diseases. T2DM had a broad peak at the categories (1) and (2), and essential HT had a peak at upper disease (the category (4)). PBC included patients in all DA categories, while AIHA did not include patients in the categories (5)–(6). The proportions of possible patients to all 650 patients were not equal among the diseases ($p < 0.0001$). The post-hoc test showed significant differences between all disease pairs ($p < 0.0001$) except the pair of PBC and AIHA ($p = 0.14$).

If the characteristics of patients in the DA categories (1)–(6) were exactly equal, the degrees of disease conviction recorded by the clinicians in EHRs would be completely random, and the classification of possible patients would not be necessary. We performed statistical analyses to assess this. Because the category (7) indicates definite CONTROLS, it will naturally have different characteristics from the other categories and was excluded from the statistical analysis. The averages of the maximum HbA1c of each patient differed significantly among the DA categories (1)–(6) (Table 3(a)). Post-hoc tests showed no significant difference for each category pair (Table 3(b)). The other lab tests’ values did not differ significantly. The other categorical variables tended to exhibit higher proportions in the category (1) than that in the categories (2)–(6) collectively, i.e., PBC billing code and no billing codes for malignant neoplasms that cause anemia (regarding AIHA, Table 3(c)).

Figure 4 shows that the performance of each GB phenotyping algorithm changed depending on the threshold of the DA category in which patients were considered as CASEs. The values of the evaluation metrics at the threshold DA category (2) (hereinafter called th(2)) indicated the values when the definite CASEs (category (1)) and probable CASEs (category (2)) were considered as CASEs. For essential HT, the recall decreased by 50% as the threshold moved from th(1) to th(2) (Figure 4(ii)). It is because that the GB algorithm(ii)(A) excluded 5 out of 13 patients in DA category (2) who had secondary HT billing codes, and that the GB algorithm(ii)(B) also excluded two patients in the category (2) (Table 2). The precision and the specificity increased by 69.2% and 13.1% from th(3) to th(4), respectively, these changes were not found in other diseases. They depended on the 90-patient increase in TP patients and concomitant decrease in FP patients, which were due to the peak at category (4) (Figure 3(ii)). In contrast, as the threshold moved from th(1) to th(6), the decrease in the NPV of PBC (0.66%) or AIHA (0.16%), and the increase in the specificity of AIHA (0.63%) were within 1% (Figure 4(iii), (iv)). PBC and AIHA had smaller in number; they account for more than 50% of upper diseases. PBC and AIHA are larger in number; they account for less than 50%.
