Zusammenfassung

Taiwan liegt entlang einer aktiven Plattengrenze zwischen der Eurasischen Platte und der Philippinischen Platte, wobei die Konvergenzrate bei etwa 80 mm/a liegt. Die anhaltende Konvergenz führt zu einer fortschreitenden Gebirgsbildung, die eine besonders komplexe Struktur aufweist. Diese Studie konzentriert sich hauptsächlich auf die strukturelle und tektonische Entwicklung des taiwanesischen Gebirgsgürtels und seines östlichen metamorphen Yuli Belt. Die Analysen und Ergebnisse in den Kapiteln 2, 3 und 4 sind im Folgenden zusammengefasst:

Die Arbeit dokumentiert die inneren strukturellen Geometrien des taiwanesischen Berggürtels sowie paläogeographische Rekonstruktionen des Eurasischen Kontinentalrands. Auf Grundlage der Ergebnisse regionaler Kartierungen und Strukturanalysen wurden drei krustenmaßstäbliche geologische Profilschnitte in verschiedenen Breiten des taiwanesischen Gebirgszuges erstellt. Die Grenzflächen zwischen Kruste und Mantel wurden auf Basis eines kürzlich erstellten 3D-Modells unter Verwendung seismologischer Daten berücksichtigt. Das im Tananao-Komplex aufgeschlossene Grundgebirge umfasst zwei Einschaltungen aus vorrangig Eurasischem Grundgebirge (Tailuko- und Yuli- Belt), die auf die känozoischen Einheiten des passiven Kontinentalrandes aufgeschoben wurden und ihrerseits tektonisch von der aus der oberen Platte stammenden sogenannten Coastal Range überlagert werden. Die Bilanzierung der Profilschnitte ergibt eine Verkürzung in den Einheiten des passiven Eurasischen Kontinentalrandes von mindestens 120 km, wobei etwa 50% des Grundgebirges, auf dem das akkretierte Material lagerte, bereits unter die Philippinische Platte subduziert wurde.

Die Dissertation befasst sich mit dem seit langem bestehenden Problem der strukturellen Geometrien und der Kinematik der tektonischen Kontakte des Yuli Belts zu den angrenzenden Einheiten. Der Yuli Belt ist im Retro-wedge des östlichen Teils des taiwanesischen Orogens aufgeschlossen. Er beinhaltet Bruchstücke einer heterogenen Einheit aus Blauschiefer-faziellen Gesteinen, die von einer stark deformierten metasedimentären Einheit mit niedrigerem Metamorphosegrad umgeben sind. Feldarbeit und mikrostrukturelle Analysen weisen auf drei Deformationsphasen im Yuli Belt hin. Auf der Grundlage von Profilschnitten und einer Überprüfung der verfügbaren P-T-t-Daten gehen wir davon aus, dass während einer ersten Deformationsphase D1 Blauschiefer-fazielle Einheiten auf niedriggradigere, Grünschiefer-

fazielle metasedimentäre Einheiten geschoben wurden. Diese Anordnung wurde später während einer zweiten Deformationsphase D2 über den zu Eurasien gehörenden Tailuko Belt entlang der Shoufeng-Verwerfung geschoben, was W-tauchende Streckungslineare auf störungsparallelen Foliationsebenen zeigen. D3 erzeugte E-vergente Falten mit W- bis NW-abtauchenden Faltenachsebenen, die frühere Foliationen sowie den D1-Deckenkontakt verfalteten. Diese E-vergente Faltung könnte mit dem entlang der Shoufeng-Verwerfung beobachteten Top-E-Rückschub zusammenhängen, der die Umorientierung von einem anfänglich E-tauchenden zu einem gegenwärtig W-tauchenden Kontakt mit sich brachte. Auf Basis geochemischer Gesamtgesteinsanalysen stellt die Blauschiefer-fazielle Einheit des Yuli Belts ein mittelmiozänes Fragment der ozeanischen Kruste und des Mantels dar, das im Südchinesischen Meer entstanden ist. Der Yuli Belt könnte daher als Teil der Suture zwischen der Eurasischen und der Philippinischen Platte betrachtet werden.

Die Deformation des Yuli Belt und der südwestlich angrenzenden Einheit, der Chulai Formation, im östlichen Zentralbereich von Taiwan wurde ebenfalls untersucht. Metamorphe Maximaltemperaturen in beiden Einheiten basierend auf Raman-spektroskopischer Geothermometrie in Verbindung mit Strukturanalysen zeigen, dass der Yuli Belt Temperaturen von ca. 400-550 °C über denen der angrenzenden Einheiten aufweist. Temperaturen > 500 °C im Yuli Belt liegen in der Nähe von drei tektonischen Hochdruckblöcken. Der Temperaturunterschied zwischen dem Yuli Belt und der Chulai-Formation erreicht über 100 °C. Es ist wahrscheinlich, dass beide Einheiten Störungsgebunden sind und dass sie nach der E-vergenten Rückfaltungsphase die gleiche Verformungsgeschichte durchlaufen haben.

Summary

Taiwan is situated along an active plate boundary between the Eurasian Plate and the Philippine Sea Plate, with a convergence rate at about 80 mm/yr. The convergence results in an ongoing mountain building that displays a structure particularly complex. This dissertation mainly focuses on the structural and tectonic evolution of the Taiwan fold-and-thrust belt and its eastern metamorphic Yuli Belt in the Central Range. The study involves geological mapping, cross-section construction and balancing, whole-rock geochemistry analysis, Raman spectroscopic geothermometry, and palaeogeographic reconstructions. Analyses and results in Chapters 2, 3, and 4 are summarized below.

Chapters 2: This work documents the internal structural geometries of the Taiwan fold-and-thrust belt and palaeogeographic reconstructions of the Eurasian margin. Three crustal-scale geological cross-sections at various latitudes of the Taiwan fold-and-thrust belt were constructed, based on results from regional mapping and structure analysis. The crust-mantle interfaces were constrained by seismological data. We interpreted three basal thrusts, namely the Pulu Tunnel Thrust (PTT), the Infra-Pulu Tunnel Thrust (IPT), and the Shoufeng Fault (SFF), which are inversion of Eurasian deep-seated rift-related extensional faults, separating the three basement imbricates. The largely Eurasian basement overthrust the Cenozoic passive margin series and which are, in turn, tectonically overlain by the upper-plate-derived Coastal Range series. The restoration of cross sections yields a minimum shortening of ca. 120 km in the Eurasian passive margin series, with about 50% of the basement, on top of which the accreted material was initially sitting, already subducted below the Philippine Sea Plate. In the paleogeographic maps, the Eurasian passive margin likely formed a slightly eastward-convex salient prior to plate convergence that created the Taiwan orogen.

Chapters 3: The thesis addresses long-standing problems of the structural geometries and kinematics of the Yuli Belt's tectonic contacts with its adjacent units. The Yuli Belt exposed is in the retro-wedge of the eastern part of the Taiwan Central Range. It hosts slivers of a heterogeneous unit of blueschist-facies metamorphic rocks that are surrounded by an intensely deformed metasedimentary unit of lower metamorphic grade. Fieldwork and microstructural analyses indicate three deformation phases in the Yuli Belt. Based on cross sections and a review of available P-T-t data, we suggest that blueschist-facies units were emplaced on top of the Yuli Belt metasedimentary unit along a thrust during a first deformation phase D1. This

assembly was later thrust over the Eurasian-derived Tailuko Belt along the Shoufeng Fault during D2, as suggested by W-plunging stretching lineations on fault-parallel foliation planes. D3 produced E-vergent folds with W- to NW-dipping axial planes, refolding earlier foliations as well as the D1 nappe contact. This E-vergent folding could be related to top-E backthrusting observed along the Shoufeng Fault, involving its reorientation from an initially E-dipping to a presently W-dipping contact. On the basis of the whole-rock geochemical data with MORB affinity, the blueschist-facies metamorphic unit of the Yuli Belt likely represents a mid-Miocene fragment formed in the South China Sea. The Yuli Belt hence could be considered as part of the suture between the Eurasian and the Philippine Sea plates.

Chapters 4: The deformation of the Yuli Belt and its southwesterly adjacent unit, the Chulai Formation, in the eastern Taiwan Central Range was also investigated. New estimates of peak metamorphic temperatures in both units using Raman spectroscopic geothermometry in relation to structural analyses show that the Yuli Belt metasedimentary unit experienced temperatures of ca. 400–550 °C higher than those of adjacent units (the Tailuko belt and the Chulai Formation). Temperatures > 500 °C in the Yuli Belt metasediments are close to three tectonic blocks that are characterized by high-pressure metamorphism. The temperature difference between the Yuli Belt and Chulai Formation reaches more than 100 °C, indicating the contact between these two units should be a fault. The Yuli Belt schist has experienced greenschist to amphibolite facies metamorphism at deeper levels, with higher estimated temperatures than the phyllitic Chulai Formation. On the basis of surface structural data and RSCM data, we interpreted an overall synformal structural position of the Yuli Belt with respect to the easterly and westerly adjacent units. This synformal geometry is likely as results of E-vergent backfolding of the Taiwan Central Range.

Chapter 1

General Introduction

1.1 Tectonic setting

Collision between oceanic island-arc terranes and passive continental margins (i.e., arc-continent collision) has been one of the most important tectonic processes in the formation of mountain belts throughout much of Earth's history (e.g., Condie, 1989; Brown and Ryan, 2011). During arc-continent collision, volcanic arcs are obducted onto continents, creating ophiolites, which are preserved along suture zones and mark the position of former oceans (e.g., Gansser, 1980; Condie, 2016). Situated in an active arc-continent collision, the Taiwan orogen is among the most studied orogens and is well known for its active and oblique collision between the Luzon Arc and the Eurasian continental margin (Figs. 1-1) (e.g., Biq, 1971; Barrier and Muller, 1984; Suppe, 1984a; Angelier, 1986; Malavieille et al., 2002). Two plates are involved in the complex tectonic setting that surrounds the Taiwan orogen (Figs. 1-1, 1-2, 1-3, 1-4): the Philippine Sea Plate to the east and the Eurasian Plate to the west. Northeast of the Taiwan area,

Fig. 1-1: Plate tectonic framework around the Taiwan-Luzon arc-continent collision. The Philippine Sea Plate moves towards the Eurasian Plate at a rate of ca. 60-90 mm/yr (e.g., Seno, 1977; Yu et al., 1997) and subducts underneath it along the Ryukyu trench. The South China Sea (part of Eurasian Plate) subducts beneath the Philippine Sea Plate along the Manila Trench.

the Philippine Sea Plate is being subducted beneath the Ryukyu arc which belongs to the Eurasian continental margin. The Okinawa backarc basin of the Ryukyu arc is developed to the north (e.g., Letouzey and Kimura, 1985) and is associated with extension and recent volcanism (e.g., Sibuet et al., 1999). South of the Taiwan island, the oceanic lithosphere of the South China Sea subducts beneath the Philippine Sea Plate, inducing the volcanism of the Luzon arc (e.g., Chen et al., 1992; Yang et al., 1995). The relative motion between the Philippine Sea Plate and the Eurasian Plate has resulted in the progressive subduction of the Chinese continental margin (Fig. 1-2) (Ustaszewski et al., 2012; Wu and Suppe, 2018), the development of the Taiwan orogen (Lee et al., 2015), and the major faults that accommodate the deformation (Wu et al., 2008b) (Fig. 1-3).

Fig. 1-2: Schematic lithosphere-scale block diagrams illustrating along-strike changes in the geometry of various crust–mantle boundaries under Taiwan (after Ustaszewski et al. 2012). Depth is given in km. (a) Geometry of the plate interface separating the Eurasian and Philippine Sea plates. The plate interface progressively steepens from south to north. (b) Section at the northern tip of Taiwan, illustrating the rollback and delamination of the subducting Eurasian lithosphere. This creates the space required for the Philippine Sea Plate to subduct northward. The deactivation of the deformation front occurs at the hinge of the subducting and delaminating Eurasian lithosphere.

The six roughly North-South oriented morpho-tectonic units of Taiwan are separated by major thrust/shear zones (Ho, 1986; Fig. 1-5). From west to east the provinces are the Coastal Plain, the Western Foothills, the Hsuehshan Range, the Backbone Slates, the Tananao Complex, and the Coastal Range. Taiwan is divided into two parts by the Longitudinal Valley Fault (LVF). West of the Longitudinal Valley Fault is the lithotectonic belts belonging to the Eurasian Plate.

Fig. 1-3: Taiwan earthquakes in the year of 1991-2017 (modified after Lee et al., 2002; Wu et al., 2008a,b). The depth and magnitude of earthquakes are from the USGS and plotted in scale. Major faults are shown in red. They may be active and responsible for earthquakes in Taiwan or regional detachment faults exist at depth (e.g., Chang et al., 1998; Shyu et al., 2005).

Fig. 1-4: Bouguer gravity anomaly map (left) and magnetic anomaly map (right) of Taiwan and its greater surroundings. Data sources: EMAG2 (Earth Magnetic Anomaly Grid in 2-arc-minute resolution; Wan, K., 2017; Briais et al., 1993) and World Gravity Map (WGM; Bomvalot et al., 2012).

East of the Longitudinal Valley Fault is the Coastal Range incorporating the accreted volcanic arc and belongs to the Philippine Sea Plate. The Taiwan mountain building process is very much alive and can be well illustrated by the rugged topography, rapid uplift and denudation, young tectonic landforms, active faulting, and numerous earthquakes (Fig. 1-3). The latest major earthquake is the devastating 1999 Chi-chi earthquake ($M_w=7.6$) with surface rupture of about 100 km in length that occurs primarily along the pre-existing Chelungpu Fault in the Western Foothills (e.g., Lee et al., 2002; Yue et al., 2005; Chapter 2, Fig. 2-6).

Fig. 1-5: Tectonic map of Taiwan (modified after Lin and Chen, 2016). Six morpho-tectonic units of Taiwan are labeled. The Tananao Complex (TC) is composed of the Tailuko Belt in the west and the Yuli Belt in the east. L.V.F.: Longitudinal Valley Fault. See Appendix D for the GIS digital supplemental map.

Subduction of the Eurasian passive margin below the Philippine Sea Plate is believed to have started from the trailing edge of the Eurasian passive margin at its transition into the South China Sea. This gave rise to pressure-dominated metamorphism, relics of which are preserved in a tectonic mélangé within in the Yuli Belt (e.g., Tsai et al., 1977; Angelier, 1986; Ustaszewski et al., 2012; Figs. 1-5, 1-6), yielding the so far youngest age for blueschists worldwide (5.1 ± 1.7 Ma; Sandmann et al., 2015). The Yuli Belt therefore is a key element in any reconstruction of the collision process of Taiwan (e.g., Zhang et al., 2020). It contains lithologically heterogeneous blueschist-facies rocks in what is referred to as tectonic or exotic blocks (e.g., Liou et al., 1977; Liou, 1981; Yui et al., 2012; Tsai et al., 2013). The high-pressure assemblages are surrounded by an intensely deformed metasedimentary unit of lower metamorphic grade metapelitic schists (e.g., Stanley et al. 1981).

Fig. 1-6: Geological map of central eastern Taiwan showing the main lithological units within the Yuli Belt and adjacent units (modified after Ho, 1988; Sandmann et al., 2015). The Chulai Formation of the Backbone Slates is exposed in the eastern range adjacent to the Yuli Belt. The Lichi Mélange flanks the southwestern border of the Coastal Range, which is composed of accreted Luzon volcanic arc edifices and deformed allochthonous forearc sedimentary sequences (e.g., Huang et al., 2006).

1.2 Motivation

Owing to oblique convergence between the Eurasian passive margin and the Luzon island arc of the Philippine Sea Plate, spatial changes across this system can be viewed as a temporal evolution from intraoceanic to continental subduction and finally continent-arc collision (e.g., Biq, 1971; Chai, 1972; Suppe, 1981). The Taiwan orogen is therefore a natural laboratory for studying the structural, metamorphic, and thermal evolution of a collision mountain belt. My research aims to better understand improperly understood aspects of the Taiwan orogeny and accretion, subduction and collision processes. There are several important questions addressed in this study, outlined in the following.

(A) Structures of the internal orogen are only very cursorily known

The structures of the Taiwan mountain belt is often presented as an imbricate fold-and-thrust belt developed in a forward breaking sequence above a shallow, east dipping basal detachment (e.g., Suppe, 1980, 1984a; Carena et al. 2002; Yue et al., 2005; Malavieille and Trullenque, 2007). The abundant data for this structural interpretation come from surface geological observations, shallow reflection seismics, borehole data, upper-crustal geophysical studies, and modeling (e.g., Suppe, 1981; Namson 1983, 1984; Yue et al., 2005; McIntosh et al., 2005). Despite the advances that have been made on the basis of surface geology (e.g., Chen and Chuang, 1989; Brown et al. 2012), upper-crustal geophysical studies (e.g., McIntosh et al., 2005), and modeling (e.g., Malavieille et al., 2019), there is still great uncertainty about the detailed structural architecture of the orogen. The structures of the internal parts of the eastern Taiwan orogen exposing metamorphic basement in the so-called Tananao Complex (including Tailuko and Yuli schists belts) have not been treated in much detail (Stanley, 1981; Yang and Wang, 1985; Fisher et al., 1999, 2007; Ho and Lo, 2015), although the western part of the Taiwan fold-and-thrust belt has been well-documented (e.g., Suppe, 1981, 1984a; Namson 1983, 1984; Suppe 1986; Mouthereau et al., 2001; Huang et al., 2004; Yue et al., 2005; Yang et al., 2006, 2007). To our knowledge, even today there are no published geological cross-sections covering the entire Taiwan orogeny that depict the structures in the Central Range in greater detail.

(B) Numerous aspects of the tectonic evolution of the Yuli Belt remain unclear

(1) The kinematics of the Shoufeng Fault, the tectonic contact between the Yuli Belt and the westerly adjacent Tailuko unit are little investigated. Because of lithologic characteristics and geographic proximity, the Shoufeng Fault was previously suggested to tentatively correlate

with the Median Tectonic Line of southwestern Japan (Yen, 1963; Ernst and Jahn 1987; Fig. 1-6). Lin et al. (1984) described the Shoufeng Fault as an NNE-striking and 70° – 80° W-dipping and topographically discernible feature, but no outcrop-scale faults were found. The recent geologic map published by Lin and Chen (2016) shows that the trace of the Shoufeng Fault has hardly been changed after Lin (1984) and Ho (1986). Chen et al. (2017) revised the fault trace ca. 60 km shorter in the south, but without providing clear arguments for this reinterpretation.

(2) The tectonic relationship between blueschist-facies units and metasedimentary rocks in the Yuli Belt is still largely uncertain. The collision of the Luzon arc with the Chinese passive margin in the Late Miocene–Early Pliocene (Ernst and Jahn, 1987; Lin et al., 2003; Mesalles et al., 2014) resulted in the exhumation of suites of differing lithologies including high-pressure mineral assemblages (Beyssac et al., 2008; Lin et al., 1984; Liou, 1981; Tsai et al., 2013; Yui and Lo, 1989). These suites have been interpreted as tectonic mélanges (Lin et al., 1984; Tsai et al., 2013). Alternatively, other researchers suggest that the tectonic blocks are allochthonous thrust sheets (Yang and Wang, 1985; Lin, 1999).

(3) Whole-rock geochemical data of the blueschist-facies assemblages yield partly intriguing results concerning the geodynamic environment in which the protoliths were formed (Island Arc or Mid Oceanic Ridge origin; e.g., Jahn et al. 1981).

(4) The tectonic relationship between the Yuli Belt high-pressure rocks and the East Taiwan Ophiolite is a matter of debate. Recent studies have contributed with a mid-Miocene protolith crystallisation age for the high-pressure metamafic blocks in the Yuli Belt (15.6 ± 0.3 Ma; Chen et al., 2017), suggesting very similar early Middle Miocene protolith ages as for the mafic rocks in the East Taiwan Ophiolite of the Lichi Mélange in the Coastal Range (14–17 Ma; Shao 2015; Hsieh et al. 2017; Huang et al. 2018; Lin et al. 2019; Fig. 1-6). As the Yuli Belt high-pressure rocks and the East Taiwan Ophiolite situated at two sides of the Longitudinal Valley Fault, the suture fault of Taiwan (Fig. 1-6), the question regarding the relationship between these two units remains.

(C) It is still debated if the Chulai Formation to the east is part of the Yuli Belt

The greenschist facies Chulai Formation of the Backbone Slates is exposed in the eastern range adjacent to the Yuli Belt (e.g., Chow and Lin, 1974; Stanley et al., 1981; Ho, 1986; Fig. 1-6). Geochronological studies on metasediments in both the Yuli Belt of the Tananao Complex (Chen et al., 2017) and its eastern adjacent Chulai Formation of the Backbone Slates (Mesalles et al., 2020) yield a youngest age peak at ca. 10–12 Ma. The two units present a stratigraphically coherent sedimentary succession but different lithologies and maximum metamorphic

temperatures. How did the Yuli Belt and the Chulai Formation form and what is the relationship between them? Notably the nature of the depositional contact (i.e., nonconformity? angular unconformity? fault?) is critical to understand the timing of the initial stage of deformation in the Central Range.

1.3 Methodology

This dissertation presents the new interpretation of three crustal-scale cross sections of the fold-and-thrust belt across the entire island of Taiwan, providing quantitative estimates on the amount of shortening that the former passive margin of the South China Sea underwent prior to its involvement in arc-continent collision at about 4 to 6 Ma ago (e.g., Chang and Chi, 1983; Suppe, 1984a; Teng, 1990; **Chapter 2**). Besides, this dissertation reinvestigated the tectonic evolution of the Yuli Belt with particular emphasis on the structural relationships between its blueschist-facies rocks, the metasedimentary unit, the westerly adjacent Tailuko Belt, and the east adjacent Chulai Formation (**Chapters 3 and 4**). Analyses and methods are summarized in the following (Fig. 1-7).

(1) Meso- and Microscale structural analysis

Structural analyses of ductile fabrics include measuring the orientation of planar and linear fabrics in the field (foliations, cleavages, stretching and intersection lineations, fold axes and axial planes) in order to determine the orientation of the finite strain ellipsoid and to deduce the kinematics of the deformation (Simpson and Schmid, 1983). Polarized light microscopy on thin sections from oriented samples (Prior et al., 1987) provides information on additional kinematic information and the succession of deformational and metamorphic events (pre-, syn- and post-tectonic mineral growth; Misch, 1969). These techniques allow us to reconstruct the relative age, conditions and kinematics of deformation (Spry, 1969) of the Taiwan fold-and-thrust belt.

(2) Geological mapping and cross-sections

The cross sections, oriented perpendicular to the regional strike of structures (bedding, thrusts, and major fold traces), were constructed using standard construction techniques (e.g., Dahlstrom, 1969; Maltman, 1990; Groshong, 2006). The thicknesses of the formation were estimated from the surface geological map, and orientations of bedding and cleavage are projected into the subsurface using dip data measured along the section. Where possible, additional constraints were placed on the structure and the stratigraphic thicknesses from published borehole data (e.g., Yue et al., 2005), Vp tomography (e.g., Wang et al., 2006; Wu et al., 2008a), as well as reflection seismic profiles (e.g., Lee J.-C. et al. 2002). The dip data of geological units were taken from geological maps and projected into the cross sections.

(3) Balanced and restored cross sections

Balancing cross sections is the most useful strategy in the interpretation of fold-thrust belts (e.g., Dahlstrom, 1969; Mitra and Namsom, 1989; Mitra, 1992). All available data are constructed and analyzed to ensure they are geometrically possible and geologically admissible, given reasonable assumptions about the pre-deformation setting and how rocks behave during deformation in a particular tectonic environment (Groshong, 2006). This strategy allows us to directly compare the restored upper-crustal stratigraphy, paleo-environments, paleogeography and structures of the restored upper crust with the underlying crustal thickness of the unfolded tomography across the shelf-slope-rise transition. Data of the aforementioned methods were used here for subsequent interpretation and synthesised in map-view restorations of the Eurasian passive margin prior to arc-continent collision.

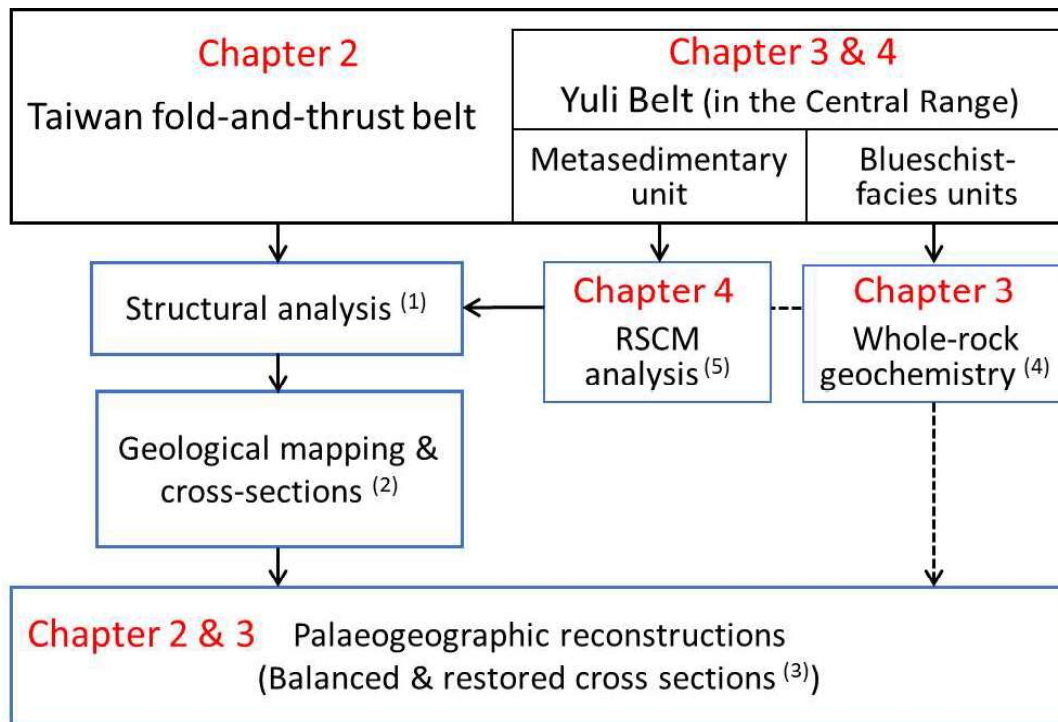

Fig. 1-7: Flow chart of research methodologies (labeled (1) ~ (5)) presented in this thesis. RSCM: Raman spectroscopy of carbonaceous material. See text for descriptions.

(4) Whole-rock geochemistry analysis

Whole-rock geochemical analyses (sixteen samples) were determined at the Institute of Geological Sciences at the Friedrich-Schiller University Jena. Major elements were determined by using ICP-OES (Inductively coupled plasma - optical emission spectrometry) after fusion with lithium borate flux. Trace elements, including the REE (rare earth elements), were analyzed by ICP-MS (Inductively coupled plasma mass spectrometry) with additional lithium

tetraborate fusion. The REE patterns and trace element compositions are essentially unaffected by metamorphism (e.g., Muecke et al., 1979; Spandler et al., 2003) in order to classify and identify the geochemical affinity and tectonic environment of the Yuli Belt high-pressure rocks. This facilitated our understanding of the modes of fore-arc subduction.

(5) Raman spectroscopy of carbonaceous material analysis

Raman spectroscopy on carbonaceous matter (RSCM) is being increasingly used as a quantitative geothermometer to estimate the maximum metamorphic temperature of the host sediments (e.g., Wopenka and Pasteris, 1993; Yui et al., 1996; Beyssac et al., 2002; Lahfid et al., 2010; Henry et al. 2019). Some studies employing RSCM across the Tananao Schist complex (e.g., Beyssac et al., 2007; Kouketsu et al., 2019) have been published, but they did not systematically include the Yuli Belt. Sixteen black metapelites/phyllites samples were collected along selected transects in the Yuli Belt and the Chulai Formation of the eastern Taiwan Central Range. RSCM was used to quantify the degree of thermal alteration of carbonaceous matter within the metasediments.

Chapter 2

Cross section balancing across the Taiwan fold-and-thrust belt for improving palaeogeographic reconstructions of the Eurasian passive margin

This manuscript is in preparation for submission.

This study was funded by the Deutsche Forschungsgemeinschaft (DFG number 380155214; granted to K. Ustaszewski, Jena and N. Froitzheim, Bonn; “Cross section balancing across the Taiwan fold-and-thrust belt”).

Abstract:

Taiwan is located along an active plate boundary between the Eurasian and Philippine Sea Plates, with convergence rates amounting to about 80 mm/yr. The island has since long served as a cradle for many tectonic concepts. Yet, the internal parts of the Taiwan fold-and-thrust belt are still improperly understood in terms of fault kinematics, internal geometries and the amount of shortening they underwent since the onset of arc-continent collision in the Mio- to Pliocene. As a consequence, geometrical restorations of the Eurasian passive margin prior to continental subduction are often guesses rather than quantitative estimates. We constructed three new crustal-scale geological cross-sections at various latitudes of the Taiwan fold-and-thrust belt, on the basis of the surface geology and crust-mantle interfaces constrained from a 3D-model employing seismological data. We interpreted three basal thrusts, namely the Pulu Tunnel Thrust (PTT), the Infra-Pulu Tunnel Thrust (IPT), and the Shoufeng Fault (SFF), which are inversion of deep-seated rift-related extensional faults, separating the pre-Cenozoic basement imbricates. The three basement imbricates overthrust the Cenozoic passive margin series and which are, in turn, tectonically overlain by the upper-plate-derived Coastal Range series. The restoration of cross sections yields a minimum shortening of 120 km in the Eurasian passive margin series, with about 50% of the basement, on top of which the accreted material was initially sitting, already subducted below the Philippine Sea Plate. When put into palaeogeographic maps, these findings imply that the Eurasian passive margin likely formed a slightly eastward-convex salient prior to plate convergence that created the Taiwan fold-and-thrust belt.

Keywords: Taiwan fold-thrust belt; crustal-scale geometry; Eurasian passive margin; subduction; palaeogeographic reconstruction

2.1 Introduction

Taiwan is located along an active plate boundary between the Eurasian and Philippine Sea Plates, which converge at about 80 mm/yr (e.g., Seno, 1977; Yu et al., 1997; Fig. 2-1). Taiwan's high-rising mountains have since long been inspiring for the development of modern ideas in structural geology, such as, e.g., the concepts of fault-related folding (Suppe and Namson, 1979), the consideration of fold-and-thrust belts as critically tapered wedges (Suppe, 1981), or links between tectonics and erosion (e.g., Willett et al., 2003; Dadson et al., 2003). Yet, the structures in the internal parts of the fold-and-thrust belt, involving the imbrication of the Eurasian distal passive margin, are still improperly understood in terms of their internal geometries and the amount of shortening they underwent since the Mio- to Pliocene. As a consequence, geometrical restorations of the Eurasian passive margin prior to continental subduction are at best educated guesses, but do not rely on quantitative estimates of thrust belt shortening (e.g., Lallemand et al., 2001; Sibuet and Hsu, 2004; Malavieille and Trullenque, 2007; von Hagke et al., 2016).

Fig. 2-1: Right: geotectonic setting around Taiwan (modified after Ustaszewski et al. (2012)). Note the progressive northward disappearance of the fore-arc basins west of the Luzon island arc. Left: plate tectonic framework around the Taiwan–Luzon arc-continent collision. The subsurface position of the lithosphere tear is taken from Ustaszewski et al. (2012). The Philippine Sea Plate is converging at a rate of ~80 mm/yr relative to Eurasia, with most of the shortening occurring within the width of the island of Taiwan (e.g., Yu et al., 1997).

Fig. 2-2: Schematic tectonostratigraphic columns portraying the tectonic units shown in the cross section B-B' of this study (modified after Brown et al. (2012)). Vertical scale is according to the time. The solid lines of Formation are constrained by previous studies of seismic, borehole, paleontological and chronostratigraphic data (e.g., Yue et al., 2005; Brown et al., 2012; Chen et al., 2017; Huang et al., 2018, and references therein). The dashed lines and the Formation without borderlines indicate unknown information and are inferred based on the geological cross sections from this paper. We conceptually treat the blueschist-facies rocks of the Yuli Belt as occupying the position of part of the suture zone separating Eurasian and Philippine Sea plates, bound by a floor thrust and roof thrust. The Longitudinal Valley Fault possibly overprinted the earlier roof thrust. High-res images are enclosed in the supplement.

In spite of an almost overwhelming amount of published studies on the Taiwan tectonics, the knowledge of present-day crustal- to lithospheric-scale geometries (e.g., Ustaszewski et al., 2012; Brown et al., 2012; Biete et al., 2018), on the petrology (e.g., Wintsch et al., 2011; Tsai et al., 2013; Baziotis et al., 2016; Keyser et al. 2016) or the geochronological evolution of Taiwan (e.g., Simoes et al., 2012; Chen et al., 2017), the structures in the internal parts of the orogen exposing metamorphic basement in the so-called Tailuko and Yuli schists belts (Fig. 2-2), are only very cursorily known (Stanley, 1981; Fisher et al., 2007; Conand et al., 2020), particularly when compared with its well-documented westernmost part of the thrust belt (e.g., Suppe, 1980, 1984a,b, 1986; Namson 1983, 1984; Mouthereau et al., 2001; Huang et al., 2004; Yue et al., 2005; Yang et al., 2006, 2007). To our knowledge, there are no published geological cross-sections covering the entire Taiwan orogeny that depict the structures in the Central Range, the metamorphic core of Taiwan, in greater detail.

In this paper we build on this theme, presenting the results of new geological mapping of the fold-and-thrust belt across the entire Taiwan, providing quantitative estimates on the amount of shortening that the former passive margin of the South China Sea underwent prior to its involvement in arc-continent collision at about 4 to 6 Ma ago (Chang and Chi, 1983; Suppe, 1984a; Teng, 1990; Yu and Chou, 2001; Lin et al., 2003; Lee et al., 2015). We go on to propose how these areas of along-strike structural change can be related to the preexisting structure of the Eurasian continental margin.

Fig. 2-3: Geological swath map across the Central Cross-island Highway of Taiwan (A-A'). The tectonic units from west to east are Coastal Plain, Western Foothills, Hsuehshan Range, Backbone Slates, Tananao Complex, and Coastal Range. Letters (a)-(l) show the localities of the outcrops in Fig. 2-4 and measurements in Fig. 2-5. Roads of the Central Cross-island Highway are shown in the black-white dashed line. High-res images are enclosed in the supplement.

2.2 Regional geology

2.2.1 Plate tectonic setting

Tectonics in the Taiwan region is characterized by the two opposite subduction systems within two plates: the eastward subduction of the South China Sea oceanic crust (on the Eurasian Plate) beneath the Philippine Sea Plate along the N-S-trending the Manila Trench, and the northward subduction of the Philippine Sea Plate beneath the Eurasian Plate along the E-W-trending Ryukyu Trench (e.g., Suppe, 1984a; Fig. 2-1). The conversion from the passive into the active margin of the Eurasian continental margin was caused by an arc-continent collision (e.g., Wu et al., 2016; Chen W.S. et al., 2017). The Eurasian continental margin (trending N 60°E) is oblique to the N-oriented Luzon Arc, and the Philippine Sea Plate moves toward 310°-305°, hence the point of the diagonal arc-continent collision migrated southward (at the rate of 84 km/m.y.; Suppe, 1984a). The onset of the collision is constrained in the late Neogene, at ~4-6.5 Ma, based on records in the foreland and intra-arc basins (Chi et al., 1981; Lin et al., 2003). The exhumation and uplift of the central part of the range since ~5-6 Ma (Lee et al., 2015; Hsu et al., 2016; Chen et al., 2018; Chen et al., 2019). Successive phases of increased exhumation rates are deduced at 5, 2-1.5 and 0.5 Ma (Mesalles et al., 2014; Lee et al., 2015; Hsu et al., 2016). The punctuated growth of the Taiwan mountains possible reveals complex relationships between the accreted South China Sea margin, the accretion of the Luzon arc/forearc as well as changes in the erosion and plate kinematics.

2.2.2 Stratigraphy

The six roughly N-S oriented morpho-tectonic units of Taiwan are separated by major thrust/shear zones (Ho, 1986; Fig. 2-2). From west to east the provinces are the Coastal Plain, the Western Foothills, the Hsuehshan Range, the Backbone Slates, the Tananao Complex, and the Coastal Range. Taiwan is divided into two parts by the Longitudinal Valley Fault (LVF) (Fig. 2-2). West of the Longitudinal Valley Fault is the lithotectonic belts belonging to the Eurasian Plate. East of the Longitudinal Valley Fault is the Coastal Range incorporating the accreted volcanic arc and belongs to the Philippine Sea Plate. Below we give an overview of the outcropping stratigraphy in the morpho-tectonic units.

(1) Coastal Plain and Western Foothills

Seismic investigations over the offshore Taiwan Strait and the inland Coastal Plain show that there are Paleogene rifting basins bounded by normal faults (e.g., Huang C. Y. et al., 2000). The Coastal Plain consists of Quaternary uplifted but undeformed poorly consolidated sediments (Figs. 2-2, 2-3). The parautochthonous strata of the Western Foothills comprises Eocene through Miocene clastic sediments of the Eurasian platform margin and latest Miocene

to Pliocene through Holocene synorogenic sediments (e.g., Teng, 1992; Fig. 2-2). The Coastal Plain and Western Foothills expose a foreland basin sequence (Lin and Watts, 2002), which deformed into generally west-verging imbricate thrust sheets and folds (e.g., Suppe 1986; Ho, 1986; Figs. 2-6, 2-9, 2-13). Because of differences in the naming and discrimination of individual formations between the 1:50,000 geological maps in the study area (e.g., Appendix A- Fig. S4), in this study we suggest the eleven sequences of Western Foothills in the central Taiwan (Figs. 2-3, 2-8) and ten sequences in the southern Taiwan (Fig. 2-11).

(2) Hsuehshan Range and Backbone Slates

The stratigraphy of the Hsuehshan Range is primarily composed of argillite, slate and sandstone. The rocks in the Hsuehshan Range are assigned to the prehnite–pumpellyite metamorphic facies with an Eocene and Oligocene age (e.g., Ho, 1986; Teng et al., 1991; Chen and Wang, 1995). It is originated from eastward-deepening grabens on the outer part of the Chinese continental margin (Teng, 1990) and complicated by a complex structure and the almost complete lack of fossils (e.g., Chen C.-T. et al., 2011; Brown et al., 2012). The Backbone Slates comprises a metamorphosed Cenozoic sedimentary slate cover, i.e., Heiyenshan/Pilushan, Tayuling and Lushan formations (Figs. 2-2, 2-3, 2-4(a)~(f), 2-8, 2-11). It is bordered to the southeast by the Longitudinal Valley Fault, the suture fault between the accreted Luzon arc and the Eurasian Plate (e.g., Conand et al., 2020). To the west, the Lishan Fault separates it from the Hsuehshan Range (e.g., Lee et al., 1997). To the east, the Basement Fault (the Pilu Tunnel Thrust, in this study) separates it from the Tananao Complex (Figs. 2-2, 2-6, 2-9, 2-13). In this study, we propose a chronostratigraphic correlation that link different rock units and facies together on the basis of age. From our mapping and cross sections stratigraphic units of the Hsuehshan Range match to the present day Heiyenshan Formation in the Backbone Slates (e.g., Teng et al., 1991), and separated to its west by the Lishan Fault, an east vergent backthrust with little offsets (Clark et al., 1993; Lee et al., 1997; Brown et al., 2012).

(3) Tananao Complex

The geological history of the Tananao Complex can be traced back to the Paleozoic and involves multiple crustal basement deformation and metamorphism in the Mesozoic and Tertiary (Ernst and Jahn, 1987). In the western part, the Tananao Complex is exposed in several thrust sheets (Tailuko Belt) with the composition of pre-Cenozoic schist and marble (Figs. 2-2; 2-4(h)~(k)). A high-grade metamorphism of upper amphibolite facies coupled with granitoid intrusions occurred during 110 to 77 Ma (e.g., Jahn et al., 1986; Fig. 2-4(k)). This thermal event is generally correlated to the westward subduction of a paleo Pacific plate beneath the Asian continental margin (e.g., Liou, 1981; Ernst et al., 1981). The tectonic contact between the

Fig. 2-4: Outcrops across various tectonics units along the Central Cross Island Highway (transect A-A', Fig. 2-3) considered representative for map-scale structures. The symbol "Y" points stratigraphically young direction from top to bottom. High-res images are enclosed in the supplement.

(a) Steeply southeast-dipping alternations of low-grade slates and thin intercalations of sandstones in the Lushan Formation. Location: Northeast Puli town, 24.006239°N, 121.111208°E.

(b) Black, low-grade metamorphic slate in the Tayuling Formation in an overturned limb, as implied by bedding-cleavage relationships (bedding dips steeper than slaty cleavage). Location: Hehuanshan east peak, 24.188053°N, 121.343847°E.

(c) Quartz veins crosscutting bedding planes (108/67) in the Heiyenshan Formation, showing deformation structures indicative of top-to-the W shear. The plunge/trend of quartz stretching lineations in quartz layers is 123/40. Location: east Tayuling, 24.180594°N, 121.357468°E.

(d) An enlargement from the square box in (c). A pinch-and-swell structure in a quartz vein indicative of layer-parallel extension in the inverted limb.

(e) Quartz-rich conglomerate with elongated quartz aggregates in bottom Heiyenshan Formation, contacting east to pre-Cenozoic formation (f). The pebbles in the conglomerate are mostly quartz, chert and feldspar with up to 1cm size. Weak foliation developed due to pressure solution. The conglomerate layer indicates the clasts might be transported from an area of high relief of a rifted continental margin. The dip direction/angle of dominant foliation is 165/51 (S1) and the plunge/trend of the elongated quartz is 155/50. Location: road bends near Bilu tunnel, 24.179117°N, 121.365897°E.

(f) Strongly foliated slaty cleavage in dark phyllites of the pre-Cenozoic Pulu Formation, marking the Pulu Tunnel Thrust. Location: road bends at east Bilu tunnel, 24.179117°N, 121.365897°E.

(g) The east-facing refolding metamorphic foliation (slaty cleavage, S1) of quartzite and sericite mylonites in the pre-Cenozoic Pulu Formation. The dip direction/angle of dominant foliation is 134/18 and the dip direction/angle of cleavage layer is 164/56. Location: road bends at west Bilu tunnel, 24.177321°N, 121.372440°E.

(h) and (i) Meta-pelites and quartzose metasandstones in the Tailuko Belt. Note how the pronounced compositional layering (S2) and stretching lineations are affected by D2 E-facing backfolding. Location: Tianxiang gorge, 24.181728°N, 121.496292°E.

(j) Refolded compositional layering (S2) of Chiuchu massive calcite marbles in the Tailuko Belt. The intersection lineations of S1 and S2 foliations are highlighted in dashed line, with plunge/trend of 217/02. Location: road bends at Lushui, 24.181068°N, 121.508318°E.

(k) The irregular contact between Chiuchu calcite marble (right) to Kanagan orthogneiss (left) in the Tailuko Belt. Marble and schist enclaves are commonly observed within the granitic rocks, suggesting intrusion into the Chiuchu Formations. Location: near Xipan, 24.170258°N, 121.578786°E.

(l) Veined meta-pelitic schists and metasandstones in the Yuli Belt affected by D2 refolding. The crenulation cleavage compositional layering (S2) are commonly observed. Location: Shoufong River, 23.837992°N, 121.388542°E.

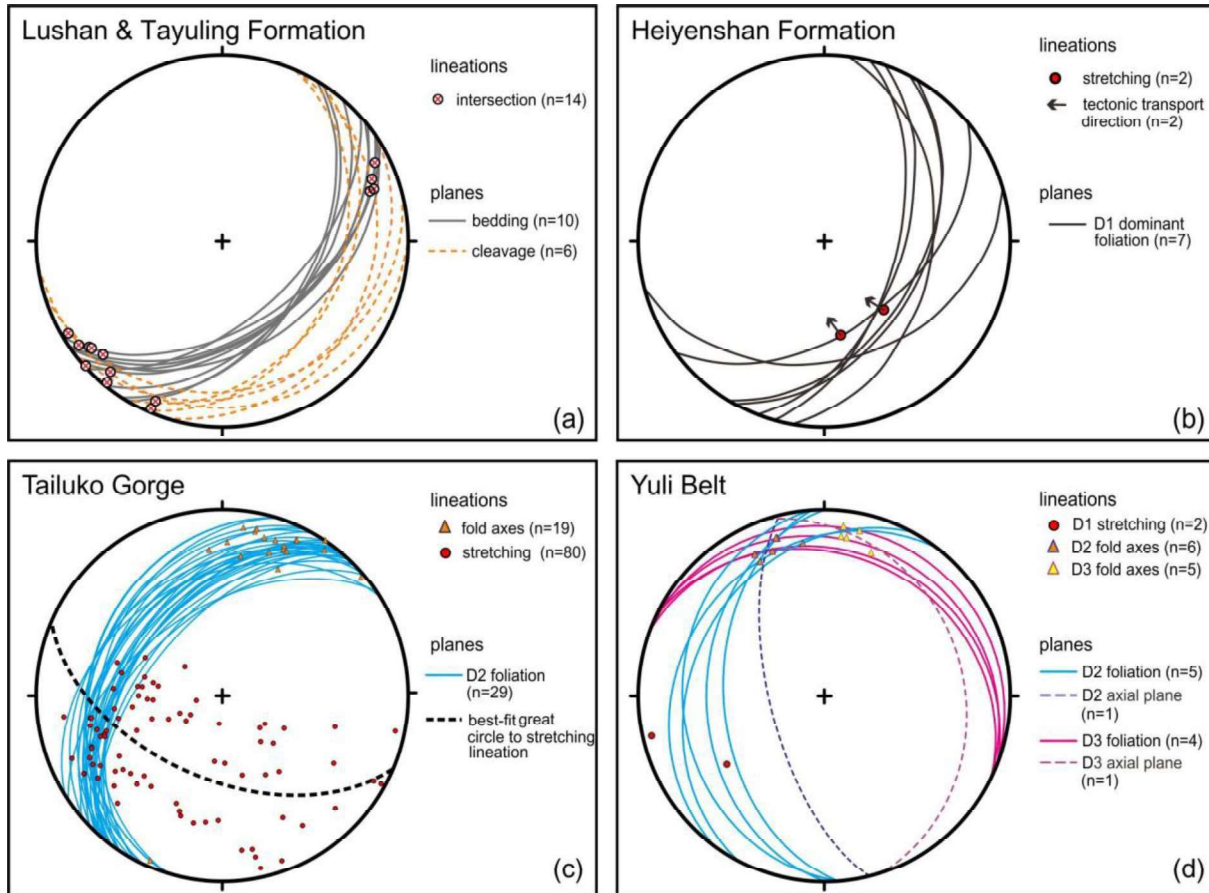

Fig. 2-5: Equal area, lower hemisphere (“Schmidt net”) projections of fabric elements across various tectonic units considered representative for the map-scale structures along the Central Cross-island Highway (Transect A-A’). Compare with Fig. 2-4 for actual outcrop geometries.

(a) Southeast-dipping bedding in the Lushan and Tayuling Formations, respectively, affected by D1 slaty cleavage. Bedding steeper than cleavage indicates overturned stratigraphy in the eastern limb of a broad syncline. Location of Lushan Formation: 24.006239°N, 121.111208; Location of Tayuling Formation: 24.188053°N, 121.343847°E.

(b) Southeast-dipping dominant foliation in the Heiyenshan Formation (D1) with top-to-the NW shear sense of the hanging wall. Location: 24.180594°N, 121.357468°E.

(c) West-dipping D2 foliation in the Tailuko Belt refolding D1 compositional layering and stretching lineations considered to have accommodated W-directed shear during D1. Compare with Figure 5 (h) and (i). Location: 24.181728°N, 121.496292°E.

(d) West dipping dominant foliation (D2) locally overprinted by north-dipping foliation (D3) in meta-sediments of the Yuli Belt along the Shoufong Hsi river. Location: 23.837992°N, 121.388542°E.

Tailuko Belt and the easterly adjacent Yuli Belt is the Shoufeng Fault (Yen, 1963). The Yuli Belt of the Tananao Complex is exposed and forms the most internal tectonic unit of the Central Range (Liou, 1981). It hosts blueschist-facies metamorphic igneous rocks embedded in an intensely deformed metasedimentary succession (e.g., Tsai et al., 2013; Keyser et al., 2016; Figs. 2-2; 2-4(i); 2-12(q)). Recent detrital zircon age spectra from metasediments of the Yuli Belt and found that they resemble Cretaceous, Eocene-Oligocene, and Miocene sediments of Taiwan (e.g., Chen et al., 2017; Mesalles et al., 2020). Consequently, they suggest that the youngest sediments in the Yuli Belt are Miocene, and that the belt represents a Miocene-age accretionary complex.

(4) Coastal Range

The Coastal Range in eastern Taiwan is the Neogene Luzon calc-alkaline arc and associated volcanogenic sediments as well as the Luzon trough forearc basin deposits (e.g., Huang et al., 2018). It comprises an upper Miocene arc basement (the Tuluanshan Formation, > 2 km thick), with a patchy occurrence of limestone at its top (the Kankou Limestone), the Late Miocene Fanshuliao Formation with less slate chips in the lower part (Chang, 1969), and the Pliocene Paliwan Formation with more slate chips disconformably in the upper part (Teng, 1979) (Fig. 2-2). A thin slice of tectonic mélangé, the Lichi Mélangé is exposed along the tectonic suture on the overriding plate (Biq, 1971). Remnants of oceanic facies (the East Taiwan Ophiolite, Hsu, 1956) that formerly lay between the Asian continental margin and the volcanic arc are preserved in exotic blocks of the Lichi Mélangé (e.g., Page and Suppe, 1981; Ernst et al., 1985; Lin et al., 2019).

Fig. 2-6: Crustal-scale geological cross section across the Central Cross-island Highway of Taiwan (A-A'), modified and extended after Lee J.-C. et al. (2002). Color-coding of geological units follows that of Fig. 2-3. The D1 west-directed transport thrust sheets are Houli thrust, Shuangtung thrust and Tili thrust from west to east, respectively. The Infra-Piliu Thrust (IPT) is interpreted as a revived half-graben normal fault, indicated by the thickness differences of both sides in the Backbone Slates unit. Piliu Tunnel Thrust divides Heiyenshan Formation of the Backbone Slates and pre-Cenozoic Piliu Formation of the Tananao Complex (with outcrop evidences in Fig.2-5 (e) and (f)). Three thrust imbricates of the internal basement were involved in crustal-scale D2 back-folding in the retro wedge of the Taiwan orogen. High-res images are enclosed in the supplement.

Fig. 2-7: (a) Crustal scale transect across the Central Cross-island Highway of Taiwan (A-A'). See Fig. 2-3 for section trace. (b) First-order restoration of the section A-A' with minimum shortening estimates. High-res images are enclosed in the supplement.

2.3 Structural geometry

The structural analyses and interpretations that follow are based on our new geological mapping (Figs. 2-3, 2-8, 2-11). This mapping is the continuation of previous work in the western and central Taiwan (e.g., Chi et al., 1981; Lee J.-C. et al. 2002; Huang S.-T. et al., 2004; Yue et al., 2005; Sandmann et al., 2015; Lin and Chen, 2016). Field mapping dataset was carried out at 1:50,000 scale using the geological maps of the Central Geological Survey of Taiwan (e.g., Yi et al., 2012) as a base. Major thrusts and stratigraphic contacts (Ho, 1986; Lin and Chen, 2016) have been correlated along strike. Three transects that are geometrically constrained from the surface geological data are presented for the middle part of Taiwan in Figs. 2-6, 2-9, 2-13. The cross sections, oriented perpendicular to the regional strike of structures (bedding, thrusts, and major fold traces), were constructed using standard construction techniques (e.g., Dahlstrom, 1969). The thicknesses of the brittle deformation are taken directly from the surface geological map, and bedding and cleavage are projected into the subsurface using dip data measured along the section. Where possible, additional constraints were placed on the structure and the stratigraphic thicknesses from published borehole data (e.g., Yue et al., 2005). The location of the basal detachment and the deep structure are determined using the geometric controls provided by the stratigraphy and wedge mechanics (e.g., Carena et al. 2002; Naylor and Sinclair 2007), Vp tomography (Wu Y.-M. et al., 2008a; Appendix A- Figs. S1-S3), as well as reflection seismic profiles (e.g., Lee J.-C. et al. 2002). In the description of the structure that follows, the study area has been divided into two deformation types with representative outcrops and structures (Figs. 2-4, 2-5, 2-12).

2.3.1 D1: west-facing folding & transport

In the pro-wedge side of the orogen, the structure of western Taiwan is similar to most compressive mountain belts in that it displays large horizontal contraction strain overlying a décollement. It has a buried thrust front (e.g., the Holi Thrust in A-A'; Fig. 2-6; the Changhua Thrust in B-B'; Fig. 2-9) and all major thrusts are interpreted to extend westward into the offshore where they form a marine accretionary complex. The surface structure of the study area is that of an imbricate westward fold-and-thrust system (D1), but with a distinct north-south change in structural architecture that is presented in detail below. In the Central Cross-island Highway of Taiwan (A-A'), the transect comprises four thrust sheets: the Holi, Sanyi, Shuangtung, and Tili thrust sheets (Figs. 2-3, 2-6); in the central Taiwan (B-B') it consists Changhua, Chelungpu, Shuangtung, and Tili thrust sheets (Figs. 2-8, 2-9); in the Southern Cross-island Highway of Taiwan (C-C'), the extensional fault system of the Eurasian continental margin are oriented at a high angle to develop imbricated fold-and-thrust belts,

consisting Chuku, Lunhou, Tatou, Hsianlin, Changshan thrust sheets (Figs. 2-11, 2-13). The west-vergent folding is a result of the bending of the thrust sheets as they ride over steps along décollements (the fault-bend folding, e.g., Suppe, 1979). A large-scale pop-up structure in the Central Cross-island Highway of Taiwan (A-A') buttresses against the Western Foothills to the west along the Tili Thrust and juxtaposed to the Backbone Slates to the east by the backthrust Lishan Fault (Fig. 2-6).

On the basis of our surface structural data (Figs. 2-3, 2-8), we interpret the Backbone Slates in the central Taiwan to be forming an over-20 km-length synclinorium structure (Figs. 2-6, 2-9), which is in good agreement with significant changes of the Vp tomography (Wu Y.-M. et al., 2008a; Appendix A- Figs. S1-S2) and the rock type. A steep to gently east to southeast dipping monocline in the slate dominated Lushan Formation (Lower Miocene) represents the western limb of the regional synclinorium in the Backbone Slates (Figs. 2-4(a), 2-6). East of the Hehuan Mountain, black, low-grade metamorphic slates of the Tayuling Formation (Oligocene-Miocene), implies an east-dipping overturned limb of the large synclinorium, where bedding dips steeper than slaty cleavage (Figs. 2-3, 2-4(b), 2-5(a), 2-6). The Heiyenshan Formation (Eocene-Oligocene) is exposed in the inverted limb at east of the Pilu Mountain and the Chilai Mountain (Fig. 2-3), showing deformation structures indicative of top-to-the W/NW shear and layer-parallel extension (Figs. 2-4(c)(d), 2-5(b), 2-6). Quartz-rich conglomerate with elongated quartz aggregates in bottom Heiyenshan Formation (Fig. 2-4(e)), contacting east to the strongly foliated Pilu Formation (pre-Cenozoic) (Fig. 2-4(f)), indicates the clasts might be transported from an area of high relief of a rifted continental margin. The westward transport direction (D1) provides important kinematic information for the Pilu Tunnel Thrust in our structural model (Figs. 2-4(g)). To maintain structural consistency in the Backbone Slates, we use the Pilushan Formation (Eocene-Oligocene), that consists of both the Tayuling and Heiyenshan Formations in the Southern Cross-island Highway of Taiwan (C-C'; Fig. 2-11). The westward transport direction (D1) is observed in the east of Yakou, showing deformation structures indicative of top-to-the WNW shear (Fig. 2-12(m) (o)), kinematically similar to the central Taiwan.

Fig. 2-10: (a) Crustal scale transect across the central Taiwan (B-B'). See Fig. 2-3 for section B-B' with minimum shortening estimates. High-res images are enclosed in the supplement.

2.3.2 D2: east-facing folding & transport

In contrast, the retro-wedge of the Taiwan orogen contains different orientations of cleavages. Rocks in the Tananao Complex that are exposed within the retro-wedge record the early deformation history (D1) which is the same as that in the pro-wedge, but the later history involves eastward backfolding and thrusting (D2), evidenced by the new developing foliations (S1) overprinting earlier foliated planes (S1) during crenulation (Figs. 2-4(h)(l), 2-5(c)(d), 2-11(p)(q), 2-12 (n)(p)(q)). In the western Central Range (Hsuehshan Range and Backbone Slates), the pervasive slaty cleavage (S1) associated with the west-vergent folds is gently southeast-dipping with NE-SW strike. Moreover, the slaty cleavage (S1) dips to the southeast but steepens near the divide or the axis of the range (Figs. 2-6, 2-9, 2-13). In the eastern Central Range (Tananao Complex), the pronounced compositional layering is tightly refolded and transposed into parallelism with S2, which dips to the west. A detailed D2 structural analysis in the Tananao Complex is presented and discussed in the Chapter 3.

2.3.3 Basement imbricates

Three crustal scale imbricates (basement units), bounded by three basal thrusts and the Longitudinal Valley Fault, are proposed in this study (Figs. 2-6, 2-9, 2-13). We interpret basal thrusts, namely the Pilu Tunnel Thrust (PTT), the Infra-Pilu Tunnel Thrust (IPT), and the Shoufeng Fault (SFF), are inversion of deep-seated rift-related extensional faults. The structural model is consistent with the consensus that the former passive margin was segmented into rift grabens and adjacent shoulders, revealing Eocene to Oligocene sedimentary successions of highly contrasting sedimentary facies and thickness in the western Central Range (Teng et al., 1991; Tilmann et al., 1992; Brown et al., 2012; Alvarez-Marron et al., 2014; Camanni et al., 2014). Below we give a description of each basal accretion unit, followed by an interpretation of the kinematic reconstructions (Figs. 2-7, 2-10, 2-14) in Section 2.4.

- ① The Infra-Pilu Tunnel Thrust basement unit is bounded by the buried Infra-Pilu Tunnel Thrust in the west and the Pilu Tunnel Thrust (Figs. 2-4(f)) in the east. It contains buried pre-Cenozoic Eurasian continental margin basement, that is overlain by Eocene to Oligocene sedimentary successions (i.e., Heiyenshan, Tayuling, and Lishan Formations) (Fig. 2-7).
- ② The Pilu Tunnel Thrust basement unit is bounded in the west by the Pilu Tunnel Thrust and in the east by the Shoufeng Fault. It is composed of predominately pre-Cenozoic Tailuko Belt in the study area, with a minor amount of Paleogene Pilu Formation cropping out in the Southern Cross-island Highway of Taiwan (C-C') (Figs. 2-11, 2-13, 2-14). We interpret the Pilu Formation to be forming the core of an east-vergent synformal structure in the transect C-C'.
- ③ The Shoufeng Fault basement unit is bounded by the Shoufeng Fault in the west, by the

Longitudinal Valley Fault in the northeast (Fig. 2-9) and by the Chulai Fault in the southeast (Fig. 2-13). We interpret the Shoufeng Fault basement unit comprises tightly refolded (and faulted) rocks of the Yuli Belt (Figs. 2-7, 2-10, 2-14), although the details of this area may be more complex with Miocene ages on detrital zircons (e.g., Chen et al. 2017) and the interaction between the high-pressure metamorphic units and the basal thrusts (e.g., Chapter 3 and 4). Following nappe stacking, these basement units were later involved in orogen-scale back-folding, leading to the development of a second, vertical to steeply W-dipping younger cleavage (S2) that overprinted older nappe-stacking related foliations (S1).

2.3.4 Normal faults and strike-slip faults

Most orogenic belts result from oblique convergence, which can result in both margin-normal (thrust faulting) and margin-parallel (strike-slip faulting) displacements. In the Taiwan orogenic belt, the along-strike extension has been observed within the eastern Central Range and interpreted as non-coaxial left lateral shear related to the strain partitioning (e.g., Faure et al. 1991; Fisher, 1999; Conand et al., 2020) or sub-horizontal lateral extrusion associated with an arcward-dipping backstop (Fisher et al. 2002; Wintsch et al. 1999). In the Yuli Belt region, the normal faults dip to the southwest or northeast and could be related to the latest shallow extension of exhumation processes. We assume that any late-stage (e.g., post penetrative strain) structures (e.g., normal or strike-slip faulting) are insignificant in the crustal-scale of this study.

Fig. 2-11: Geological swath map across the Southern Cross-island Highway of Taiwan (C-C'). Letters (m)-(q) show the localities of the outcrops in Fig. 2-12 and measurements projected in the "Schmidt net". Roads of the Southern Cross-island Highway are shown in the black-white dashed line. High-res images are enclosed in the supplement.

Fig. 2-12: Outcrops across various tectonics units along the Southern Cross Island Highway (transect C-C', Fig. 2-11) considered representative for map-scale structures.

(m) East-dipping veined quartz feldspar schists in the Pilushan Formation affected by D1 folding, showing deformation structures indicative of top-to-the WNW shear, similar to Fig. 2-4(c). Location: west Litao, 23.242931°N, 120.991406°E.

(n) The east-facing refolding metamorphic foliation (slaty cleavage, S1) of quartzite slate and dark phyllites in the Pilushan Formation. The refolded S2 foliation dips to the west. Location: east Litao, 23.191908°N, 121.018261°E.

(o) Folded bedding (S0) of black, low-grade metamorphic slate in the Pilushan Formation. An over 10 m-wavelength overturned anticline exposed at the roadside of east Litao, as implied by bedding-cleavage relationships. The fold axial plan is east-dipping. Location: 23.191908°N, 121.018261°E.

(p) WNW-dipping meta-pelites of Yuli Belt contact with epidote chlorite schists in the Tailuko Belt. Both Formations show the same dip of S2 foliation. Location: 200m east of Xinwu Bridge, 23.1359°N, 121.114°E.

(q) Veined meta-pelitic schists and metasandstones in the Yuli Belt affected by D2 refolding, similar to Figure 4 (l). Location: SE Chulai village along road 20, 23.1285°N, 121.116°E.

Fig. 2-13: Crustal-scale geological cross section across the Southern Cross-island Highway of Taiwan (C-C'), modified and extended after Huang S.-T. et al. (2004) and Chi et al. (1981). Color-coding of geological units follows that of Fig. 2-11. Crust-mantle boundaries after Ustaszewski et al. (2012). High-res images are enclosed in the supplement.

Fig. 2-14: (a) Crustal scale transect across the Southern Cross-island Highway of Taiwan (C-C'). See Fig. 2-11 for section trace. (b) First-order restoration of the section C-C' in with minimum shortening estimates. High-res images are enclosed in the supplement.

2.4 Palaeogeographic reconstructions of the Eurasian margin

We construct balanced and restored cross sections (Figs. 2-7, 2-10, 2-14) using classical line-length (in brittle units) and equal area-balancing (in ductile units) approaches aim to assure the viability of the structural interpretation. Minimum shortening estimations in the three cross sections, which is a by-product of their balancing and restoration, are also presented (Figs. 2-14, 2-15, 2-16). The reactivation and inversion of faults derived from the Eurasian continental margin have been shown to be particularly crucial in Taiwan orogeny (e.g., Mouthereau et al., 2006). Based on the analysis of the Cenozoic stratigraphy in Hsuehshan Range, Backbone Slates, and Tananao Complex (Fig. 2-2), the rifting phase predates the Late Oligocene to Miocene break-up and drifting in the South China Sea (Teng and Lin, 2004). Contraction was triggered by subduction of the Eurasian passive margin below the Philippine Sea Plate (Tsai et

Fig. 2-15: The extended lines (A-A', B-B', C-C') of three restorations of the Eurasian section in Figs. 2-7, 2-10, 2-14 with minimum shortening estimates derived from line-length and area-balancing in the Cenozoic and pre-Cenozoic succession. The former continent-ocean boundary (COB) is reconstructed on the basis of shortening estimates of the three transects. The topography base map follows that of Fig. 2-1.

al., 1977; Angelier, 1986; Lallemand et al., 2001; Ustaszewski et al., 2012). A number of extensional faults in this study that developed along the outer part of the margin and its slope can be traced on land (e.g., the Sanyi, Shuangtung, and Tili thrusts in Figs. 2-7, 2-10, 2-14; Yang et al., 2006, 2016), where they have been shown to affect the structure of the foreland thrust-and-fold belt (Alvarez-Marron et al., 2014; Brown et al., 2017; Camanni et al., 2016; Rodriguez-Roa & Wiltschko, 2010; Suppe, 1986; Yang et al., 2007, 2016). Our own interpretation considers the Tailuko and Yuli belts as comprising two crustal scale imbricates of Eurasian basement that form the tectonically highest units and which overthrust the Cenozoic passive margin series (Figs. 2-7, 2-10, 2-14). They were juxtaposed along a West-vergent thrust contact soon after collision.

The restored version of three cross sections yields the shortening amount of the former passive margin of Eurasia at least ~120 km, ~120 km, and ~140 km in A-A', B-B', and C-C', respectively (Fig. 2-15). The position of the plate interface along this transect, constrained from geophysical data (Ustaszewski et al., 2012; Fig. 2-1), implies that over half of the basement, on top of which the accreted material was initially sitting, has entered subduction ("subducted crust"). Therefore, the former continent-ocean boundary (COB) is reconstructed before subducting in Fig. 2-16, which is consistent with the underlying unfolded passive margin tomography (e.g., Chen, 1995, Rau and Wu, 1995). In the paleogeographic maps, the Eurasian passive margin likely formed a slightly eastward-convex salient prior to plate convergence that created the Taiwan fold-and-thrust belt.

Fig. 2-16: Paleogeographic reconstructions of the Eurasian passive margin in the map view. The former continent-ocean boundary (COB) is reconstructed on the basis of shortening estimates of the three transects (A-A', B-B', C-C'). a: Present-day plate tectonic map around Taiwan. b: Paleogeographic reconstruction for 15 Ma (Chapter 3). We selected the framework of a global plate reconstruction of Wu and Suppe (2018) using a hybrid absolute reference frame that includes moving Indian/Atlantic hotspots and a true polar wander corrected paleomagnetic-based model (Seton et al., 2012).

2.5 Conclusions

On the basis of our new surface geological mapping, we interpret the structure of three transects across the entire Taiwan to be two deformation types (D1 and D2) with three basement imbricates. D1 type is an imbricate westward fold-and-thrust system, which develops in the Coastal Plain, Western Foothills, Hsuehshan Range and Backbone Slates. In the western Central Range, the pervasive slaty cleavage (S1) associated with the west-vergent folds is gently southeast-dipping with NE-SW strike. D2 type is an east-facing backfolding and backthrusting system in the eastern Central Range, leading to the development of a second, vertical to steeply W-dipping younger cleavage (S2) that overprinted older nappe-stacking related foliations (S1). Three crustal scale basement imbricates are bounded by three basal thrusts and the Longitudinal Valley Fault. Following nappe stacking accretion, these basement units were later involved in orogen-scale D2 backfolding and backthrusting in structural architecture. In our balanced and restored cross sections, we estimate the minimum shortening of the former passive margin of Eurasia to be ~120 km in the central and ~140 km in the south. Over half of the basement, on top of which the accreted material was initially sitting, has entered subduction. In the paleogeographic maps, the Eurasian passive margin likely formed a slightly eastward-convex salient prior to plate convergence that created the Taiwan fold-and-thrust belt.

Chapter 3

The Yuli Belt in Taiwan: part of the suture zone separating Eurasian and Philippine Sea plates

This Chapter is an extended version of the manuscript published in “Terrestrial, Atmospheric and Oceanic Sciences”.

Zhang, Y., Tsai, C.-H., Froitzheim, N., Ustaszewski, K. (2020): The Yuli Belt in Taiwan: part of the suture zone separating Eurasian and Philippine Sea plates. *Terrestrial, Atmospheric and Oceanic Sciences*, 31, 1-18, doi: 10.3319/TAO.2020.06.28.01

Abstract:

The Yuli Belt exposed in the retro-wedge of the eastern part of the Taiwan orogen hosts slivers of a heterogeneous unit of blueschist-facies rocks. However, the question pertaining to its palaeogeographic provenance is still debated despite new geochronological data. This is largely because the structural geometries and kinematics of the Yuli Belt’s tectonic contacts with its adjacent units are improperly understood. This paper presents new structural data from field work along several river transects in the Yuli Belt, which we combine with published data into a new tectonic model. Fieldwork and microstructural analyses indicate three deformation phases in the Yuli Belt. Based on cross sections and a review of available P-T-t data, we suspect that blueschist-facies units could have been emplaced on top of greenschist-facies metasedimentary units along a thrust during a first deformation phase D1. This assembly was later thrust over the Eurasian-derived Tailuko Belt along the Shoufeng Fault during D2, as suggested by W-plunging stretching lineations on fault-parallel foliation planes. D3 produced E-vergent folds with W- to NW-dipping axial planes, refolding earlier foliations as well as the D1 nappe contact. We suspect that this E-vergent folding could be related to top-E backthrusting observed along the Shoufeng Fault, involving its reorientation from an initially E-dipping to a presently W-dipping contact. On the basis of the whole-rock geochemical data with MORB affinity, the blueschist-facies metamorphic unit of the Yuli Belt likely represents a mid-Miocene fragment of oceanic crust and mantle issued in the South China Sea. It could hence be considered as part of the suture between the Eurasian and the Philippine Sea plates.

3.1 Introduction

Sutures or suture zones are variably sized allochthonous tectonic units occurring in every collisional orogen, separating tectonic units of contrasting palaeogeographic origin (Gansser, 1964 and 1980; Dewey, 1987, Grasemann and Huet, 2016). They typically contain ophiolitic fragments that represent relics of formerly larger amounts of oceanic crust and mantle lithosphere initially separating the continental units before subduction (Moores 1970; Moores and Vine 1971; Gansser, 1980; Condie, 2016). Put more simply, sutures are fossil collisional plate boundaries. Quite often, sutures form brittle or mylonitic shear zones that accommodated large amounts of contractional strain, providing testimony of plate convergence. Sutures regularly represent strongly tectonised zones with large lithological and metamorphic heterogeneity of mappable units, which are furthermore often spatially disrupted. Among the many heterogeneous lithologies encountered in suture zones, high-pressure metamorphosed rocks always receive particular attention, because they provide undisputable proof for subduction processes preceding collision (e.g., Stern, 2005). This is also the case for the famous Yuli Belt of Taiwan, a tectonic unit on the eastern side of Taiwan's Central Range (Fig. 3-1). Its occurrences of blueschist-facies rocks have been the focus of continued petrological and geochronological investigations since the pioneering work of Yen (1959). The Yuli Belt contains lithologically heterogeneous blueschist-facies rocks in what is referred to as tectonic or exotic blocks (Table 3-1), which, according to numerous authors (e.g., Liou et al., 1977; Liou, 1981; Yui et al. 2012; Tsai et al. 2013), are surrounded by an intensely deformed metasedimentary unit of lower metamorphic grade (Table 3-1). Internally, some of the high-pressure blocks are considered tectonic mélanges themselves, exhibiting four petrographically different types of glaucophane-bearing rocks (Tsai et al., 2013) with intervening metasediments such as garnet-bearing blackschists (Beyssac et al., 2008) or garnet paragonite mica schists (Keyser et al. 2016). Recent geochronological work on the blueschists has yielded a Lu-Hf age of 5.1 ± 1.7 Ma (Sandmann et al. 2015; see Table 3-2 for an overview of hitherto obtained geochronological data from the Yuli Belt) – rendering it one of the youngest blueschists belts worldwide (Ota and Kaneko 2010).

The metasedimentary unit of the Yuli Belt (i.e., all units other than the aforementioned blueschist-bearing tectonic blocks) has been differentiated into four units, according to Taiwan's Central Geological Survey (Wang 1992; Yi et al. 2012), namely the Hutoushan Schists, Senjung Schists, Hungyeh Schists, and Albite spotted Schists (Juisui Schists). In the case of the first three units, lack of metamorphic index minerals and lithological similarities (mostly metapelitic to metapsammitic schists with variable amounts of carbonaceous matter) make it challenging to map differences between these lower amphibolite- to greenschist-facies

Fig. 3-1: Plate tectonic map of Taiwan and its greater surroundings showing main tectonic units. The Philippine Sea Plate moves towards the Eurasian Plate at a rate of c. 60-90 mm/yr and subducts underneath it along the Ryukyu trench. The South China Sea (part of Eurasian Plate) subducts beneath the Philippine Sea Plate along the Manila Trench. The extinct South China Sea spreading ridge and magnetic lineations after Yeh et al. (2012); global topography model ETOPO1 (Amante and Eakins, 2009); continent-ocean boundary (COB) from Sibuet et al. (2016).

units in terms of their structural position within the Yuli Belt. The sole more diagnostic lithology within the metasedimentary unit are the albite-bearing spotted schists (e.g., Yang and Wang 1985; see Table 3-1 for further references; Fig. 3-4). The Yuli Belt has long been considered an exhumed portion of the Eurasian pre-Cenozoic basement, partly based on geochronological data indicating Cretaceous ages for metamorphism (Jahn and Liou 1977; Jahn et al. 1981; Lo and Yui 1996). However, recently geochronological data called for a reinterpretation (Fig. 3-2; Table 3-2). Chen et al. (2017, 2019) demonstrated that they contain detrital zircons as young as the middle Miocene, suggesting that the whole Yuli Belt schists as a part of Backbone Range extruded and exhumed prior to the arc-continent collision at ~12 Ma, which is much older than the previously determined onset age of Taiwan mountain building of

~4-6 Ma (e.g. Chang and Chi 1983; Lee et al. 2015). With respect to the blueschist-facies rocks that the metasedimentary succession hosting, zircon U-Pb in-situ ICP-MS dating in exotic blueschists, also from Tamayen (Fig. 3-4), yielded protolith ages as young as 15.4~16.0 Ma (Chen et al. 2017; Lo et al. 2020), proving the concept of a pre-Cenozoic age for the Yuli Belt meta-igneous rocks most likely wrong. Lo (2018) also broadcasted the crystallization ages of metaplagiogranite in the Chisui Hsi area with c. 13 ~ 15 Ma by using zircon U-Pb in-situ ICP-MS dating.

Geologic time scale after Gradstein et al. (2012)

Meanwhile, numerous aspects of the tectonics of the Yuli Belt remain unclear. The kinematics of the Shoufeng Fault, the tectonic contact between the Yuli Belt and the westerly adjacent Tailuko unit (Yen, 1963), are little investigated. Lin et al. (1984) described the Shoufeng Fault as an NNE-striking and 70°~80° W-dipping and topographically discernible feature, but no outcrop-scale faults were found. Recent geological maps (e.g., Lin and Chen 2016) depict the Shoufeng Fault essentially unchanged since Ho (1986). Chen et al. (2017) revised the fault trace (Fig. 3-4), but without providing clear arguments for this reinterpretation. Also, the tectonic relationship between blueschist-facies units and the metasedimentary unit is poorly constrained. Furthermore, whole-rock geochemical data of the blueschist-facies assemblages yield partly intriguing results concerning the geodynamic environment in which the protoliths were issued (Island Arc vs. Mid Oceanic Ridge origin; e.g. Jahn et al. 1981).

In this study, we reinvestigated the tectonic evolution of the Yuli Belt with particular emphasis on the structural relationships between its blueschist-facies rocks and the metasedimentary unit. We build on recent geochronological results (e.g. Chen et al., 2017), incorporating own structural data from several river transects. Three new cross-sections across the Yuli Belt were constructed, suggesting that the blueschist-facies unit tectonically overlies the metasedimentary unit along a thrust that was later tightly folded together with the adjacent units of the Yuli Belt. We present more definitive whole rock geochemistry data from three tectonic blocks of Yuli Belt and explore the spatial and temporal relationships among the high-pressure blocks, the East Taiwan Ophiolite of the Lichi Mélange (Table 3-2), the oceanic crust of the South China Sea, and the incipient Luzon arc. Finally, relying on a simple plate tectonic reconstruction, we suggest that the Yuli Belt high-pressure unit could have originated from the oceanic crust of the South China Sea before its subduction below the Philippine Sea Plate. Since this unit at present occupies a structural position between series derived from Eurasia and those from the Philippine Sea Plate, it represents as part of the suture zone.

Fig. 3-3: Schematic tectonostratigraphic columns portraying the stratigraphic ranges of the major tectonic units and their mutual fault-bound relationships shown (based and modified after Yue et al., 2005; Brown et al., 2012; Chen et al., 2017; Huang et al., 2018, and references therein). We conceptually treat the blueschist-facies rocks of the Yuli Belt as occupying the position of part of the suture zone separating Eurasian and Philippine Sea plates, bound by a floor thrust and roof thrust. The Longitudinal Valley Fault possibly overprinted the earlier roof thrust.

Fig. 3-4: Geological map of the metamorphic units exposed in the eastern part of Taiwan's Central Range (modified after Lin and Chen 2016). The Lichi Mélangé is after Huang et al. (2006). The Yuli Belt hosts exotic blueschist-facies meta-igneous and ultramafic rocks (Hm) that we consider tectonically emplaced on top of an amphibolite- to greenschist-facies, polyphasely deformed metasedimentary unit (YI). The diagonally dashed area of the Yuli Belt is adopted from Chen et al. 2017. Occurrences of spotted schists (Sp) are based on Yi et al. (2012) and Lo (2018). Locations of outcrops in Fig. 3-7 and thin sections in Fig. 3-9 are marked by small letters. Longitudinal Valley Fault (LVF) is from Shyu et al. (2005). Geological units outside Tananao Complex and Chulai Formation are not differentiated. Sources for the geochronological data in superscripts: 1: 3.3 ± 1.7 Ma (Yui et al. 2014); 2: 5.1 ± 1.7 Ma (Sandmann et al. 2015); 3: 15.4-16.0 Ma for blueschist; 1900-1700 Ma, 1000-900 Ma, 850-700 Ma, 200-65 Ma and 65-8 Ma for metasediments (Chen et al. 2017).

3.2 Plate tectonic setting and regional geology

Several geodynamic events have shaped Taiwan throughout the Cenozoic (Fig. 3-2). The collision between the Eurasian passive continental margin and the Luzon island arc of the overriding Philippine Sea Plate (PSP) formed (and keeps forming) the spectacular topography of the Taiwan mountain belt since about 4 to 6 Ma (Chang and Chi 1983; Suppe 1984a; Teng; 1990; Yu and Chou 2001; Lee et al. 2015; Fig. 3-1). The Philippine Sea Plate moves towards NW at 60~90 mm/yr (e.g., Seno 1977; Yu et al. 1997). In the south of Taiwan, Eurasian lithosphere subducts southeastward underneath the Philippine Sea Plate. This geometry is inherited from the intra-oceanic subduction of South China Sea lithosphere underneath the Philippine Sea Plate, which commenced after the end of spreading in the South China Sea at around the early Middle Miocene (c. 16 Ma; Taylor and Hayes 1983; Sibuet et al. 2002; Fig. 3-2). While intra-oceanic subduction still prevails south of Taiwan along the Manila trench (e.g., Angelier 1986; Malavieille et al. 2002; Reed et al. 1992), advanced collisional shortening on the island of Taiwan has already led to the exposure of blueschist-facies rocks in the Yuli Belt of the eastern Central Range (Huang et al. 2006; Yui et al. 2012; Fig. 3-1).

Spreading of the South China Sea commenced at approximately 34 Ma (e.g., IODP Site U1435; Li et al. 2017) and stopped at c. 15.5 Ma (based on magnetic anomalies; Taylor and Hayes 1983; Briais et al. 1993; Sibuet et al. 2002). Subsequently, the oceanic lithosphere of the South China Sea started subducting under the Philippine Sea Plate as early as c. 15~16 Ma (Huang et al. 2006). This was inferred from ages of island arc magmas from Taiwan's Coastal Range, which forms a northward extension of the Luzon arc. Magmatism in the Coastal Range commenced in Early to Middle Miocene, as recorded by Rb-Sr, K-Ar, Ar-Ar, and fission track geochronological studies (e.g., Lo et al. 1994; Richard et al. 1986; Juang and Chen 1990; Chi et al. 1981). This is supported by more recently obtained U-Pb zircon ages of c. 14.2 Ma in the Chimei complex (Shao 2015). Geochronological studies on the East Taiwan Ophiolite (ETO) contained Lichi Mélange yielded U - Pb magmatic zircon ages of 14~17 Ma (Shao 2015; Hsieh et al. 2017; Huang et al. 2018; Lin et al. 2019). Similar ages of 15.6 ± 0.3 and 16.0 Ma were also obtained by the U-Pb dating of zircons from blueschists in the Yuli Belt (Chen et al. 2017), suggesting very similar early Middle Miocene protolith ages as for the mafic rocks in the ETO (Table 3-1).

The five major morphotectonic units making up the Taiwan mountain belt are illustrated as tectonostratigraphic columns in Fig. 3-3 (Ho 1986; Chen and Wang 1995). From west to east and separated by major faults, these are the Western Foothills, the Hsuehshan Range, the Backbone Slates, the Tananao Complex, and the Coastal Range. Tananao Complex and Coastal

Range are separated by the Longitudinal Valley Fault (LVF, Fig. 3-3). Units west of the LVF are derived from the Eurasian Plate. The Western Foothills, the Hsuehshan Range, and the Backbone Slates comprise the imbricated parautochthonous Cenozoic passive margin sequence of sandstones, conglomerates, argillites and slates structurally below the Tananao Complex (e.g., Yue et al. 2005; Beyssac et al. 2008). The deformation of those three imbricates involves the pro-wedge of Taiwan fold-and-thrust belt with the earliest fabrics of east-dipping bedding planes (S0) and slaty cleavage (S1) (e.g., Pelletier and Hu 1984; Fisher et al. 2007; Naylor and Sinclair 2007; Appendix B- Table S1). East of the LVF is the Coastal Range, consisting of Neogene calc-alkaline arc volcanics and associated volcanodetrital sediments, as well as the Huatung forearc basin deposits (e.g., Huang et al. 2018). A progressive increase in continental contamination of andesitic magmas correlates with progressively younger ages in Coastal Range volcanic rocks (e.g., Chi et al. 1981; Dorsey 1992; Shao et al. 2015). The transition from oceanic to incipient continental subduction induced the subduction of a slice of the forearc lithosphere (e.g., Malavieille et al., 2002; Wu et al. 2008; Sandmann et al. 2015). The forearc lithosphere belonging to the Philippine Sea Plate is suspected to subduct beneath the Coastal Range at about 22°N and is probably absent north of 24°N, shortly before the cessation of island-arc magmatism (Kao et al. 2000; Sibuet et al. 2002; Shyu et al., 2011).

The Tananao Complex crops out as a narrow belt west of the LVF and bears evidence of polymetamorphism and multiple deformations (e.g., Ernst and Jahn 1987). Traditional nomenclature subdivides the Tananao Complex into the western Tailuko Belt and the eastern Yuli Belt (Ho 1986; Chen and Wang 1995), separated by the Shoufeng Fault (Yen 1963, Figs. 3-3 and 4). The Tailuko Belt consists of Permian marbles, variegated Mesozoic metapelites, and greenschists (Liou 1981), intruded by the Late Cretaceous Kanagan granitic gneiss (Jahn 1986; Fig. 3-3). The Yuli Belt is dominantly composed of greenschist facies, often highly carbonaceous quartz-mica schists with blocks of metabasites up to blueschist facies (Fig. 3-4). Three larger exposures of these blocks are the Wanjun, Juisui, and Chinsui Hsi areas (Yen 1963; Liou et al. 1975; Liou and Ernst 1984; Tsai et al., 2013; Table 3-2 and Fig. 3-4). The Yuli Belt's eastern contact with the Eocene (?) Chulai/Pilushan Formation of the Backbone Slates is a sharp boundary in terms of lithology and metamorphic grade, previously interpreted as an unconformity (Stanley et al. 1981; Ho 1986). However, based on comparable ages on detrital zircons from the Yuli Belt metasediments and the northern part of the Chulai Formation (Lin and Chen 2016) as young as Miocene, the Chulai Formation has been reinterpreted as part of the metasediments of the Yuli Belt (e.g., Chen et al. 2017; Chen et al. 2019; Conand et al. 2020).

Fig. 3-5: Geological map and the cross-section A-B of the Hunyeh Hsi area. The floor thrust (Juihsi Fault) separates the blueschist-facies units from metasediments and is interpreted as a floor thrust of a suture zone. Topographic contours in this and the following figure in grey. See Fig. 3-4 for location.

3.3 New meso- to microscale observations in the Yuli Belt

3.3.1 Mesoscale structures in the metasedimentary unit

We made new outcrop-scale structural observations in the metasedimentary unit along several rivers crossing the Yuli Belt (Fig. 3-4). Mutual overprinting relationships between the observed structural elements suggest that they were formed during three successive deformation phases, termed D1, D2, and D3 in the following (Figs. 3-5, 6, 7 and 8). The S1 foliation forms a compositional layering, discernible for instance in the often graphite-rich metapelites to metasandstones in the Mugua Hsi area, where it is found to be overprinted by a moderately NW- to W-dipping S2 foliation developing a spaced crenulation or pressure-solution cleavage (Fig. 3-7a and Fig. 3-8a). Closer to the Shoufeng Fault, e.g. along the Shoufeng Hsi itself, S2 foliations usually form a more densely spaced and pervasive W- to NW-dipping compositional layering (Fig. 3-8b), carrying rare WSW-plunging stretching lineations (Fig. 3-8b) that we tentatively interpret as being associated with shear displacement along the Shoufeng Fault itself during deformation phase D2 or D3 (Fig. 3-4).

We found S2 to be often folded during a later deformation phase D3 (Fig. 3-7 b, c, d and Fig. 3-8b). On the outcrop scale, the intensity of this D3 deformation depends on the lithology. S3 foliations form an open axial plane to crenulation cleavage that is well-developed in the metapelitic layers, and absent in the metapsammities (Fig. 3-7b) owing to the competence contrast. In proximity to the Shoufeng fault, axial planes dip clearly to the west (Fig. 3-8 top right). On a regional scale, we interpret S3 to form gently to moderately W-dipping axial planes associated with kilometer-scale E-vergent folding of the entire Yuli Belt succession (Figs. 3-5 and 6), most likely in conjunction with a major phase of E-facing back-folding of eastern parts of the Taiwan orogen (Yeh, 2004; Fisher et al., 2007), termed here D3.

Cross section A-B (Fig. 3-5) also portrays a late-stage brittle normal fault (Hungyeh Hsi Fault), but with only minor offset and hence considered of no importance here. In general, however, late stage brittle faulting is well documented in the eastern Central Range (e.g., Crespi et al. 1996; Appendix B- Table S1).

Fig. 3-6: Geological map and cross sections (C-D and E-F) of the Lakulaku Hsi and Chinsui Hsi area. See Fig. 3-4 for location.

Fig. 3-7: Outcrops of polyphasely deformed metapelites and metapsammities in the Yuli Belt (a-f) considered representative for map-scale structures. Location: (a) Mugua Hsi (23.969540°N, 121.481748°E); (b) and (c) Hunyeh Hsi (23.509600°N, 121.325941°E); (d) Lakulaku Hsi (23.310988°N, 121.248190°E); (e) and (f) Xinwuliu Hsi (23.136959°N, 121.124392°E). (g) and (h) refer to areas where microscopic samples were taken (Fig. 3-9).

3.3.2 Shoufeng Fault

Previous maps have depicted the Shoufeng Fault as a quasi-vertical planar discontinuity separating Tailuko and Yuli Belts. We dare making the remark that such a map pattern was in clear violation of the actually observed gently NW- to W-dipping S2 foliations in several river transects (Figs. 3-4, 5 and 6). We have hence felt it necessary to partly remap the trace of the northern segment of the Shoufeng Fault to better agree with actual foliation dips (Fig. 3-4). The southern part of the Shoufeng Fault as shown in Fig. 3-4 still follows the interpretations of Lin and Chen (2016), but also depicts the alternative trace suggested by Chen et al. (2017; Fig. 3-4, thinly dashed red line). Dip direction and dip of S2 foliations are mostly W- to NW-dipping and remain constant across the contact. Also, the lithological and fabric transitions across this fault (e.g., Kuyuan schist of Tailuko Belt and Yuli Belt metasedimentary unit, along Hunyeh Hsi and Lakulaku Hsi, Fig. 3-4, Fig. 3-6, Fig. 3-8) are gradual. Both Kuyuan Schist and Yuli Belt metasedimentary unit are very similar to undistinguishable in the field as they are mainly composed quartz-mica schists. We suspect that the juxtaposition of Yuli and Tailuko Belts across the Shoufeng Fault may have occurred during an early W-directed transport direction (D2 phase). This interpretation is made on the notion that the Yuli Belt metasediments experienced elevated pressures of up to 1.5 GPa (Conand et al. 2020), which have not been reported in the westerly adjacent Tailuko Belt. We suspect that the Shoufeng Fault became reoriented and reactivated with an opposite slip sense during a later phase of E-vergent backfolding (termed here D3 phase; Fig. 3-7e, f). Evidence for such top-SE shear was found in an outcrop of spotted schists from Xinwuliu Hsi, close to the Shoufeng Fault (Fig. 3-7e, f and Fig. 3-9h). There, S-C' fabrics with a C-foliation (317/46) and C' shear bands (282/31) have accommodated SE directed shear (Fig. 3-7e, f, Fig. 3-9h). We interpret these top-SE senses of shear to also belong to D3 phase of backfolding, which overprints earlier (D2) top-W emplacement fabrics along the Shoufeng fault.

3.3.3 Microstructural observations from the spotted schist subunit

The mineralogically most distinctive unit within the metasedimentary unit of the Yuli Belt is the albite spotted schists, separately mapped in Fig. 3-4, relying on Lin et al. (1984), Yi et al. (2012) and Lo (2018). The spots in these metapelites are formed by albite and - to a smaller amount - garnet and titanite porphyroblasts (Yang and Wang 1985; Fig. 3-9). The characteristic mineral assemblage of these schists is albite, garnet, muscovite, chlorite, titanite, \pm tourmaline, \pm calcite and \pm rutile (Chiang 2003), as well as a variable amount of carbonaceous matter. Our observations suggest that the growth of albite porphyroblasts with graphitic inclusions predated the formation of the S3 foliation. This is evidenced in a sample from the Juisui/Hunyeh Hsi area (Fig. 3-9 g), which shows that asymmetrically rotated albite with graphitic inclusions and

chlorite in pressure shadows forms a porphyroclast with respect to the older S2 foliation. In the sample from Xinwuliu Hsi, albite and titanite form porphyroclasts that are pre-kinematic with respect to the younger foliation (Fig. 3-9 h). This younger foliation forms pervasive C-planes with enrichment of carbonaceous material. S-C' type of shearing clearly transposes an older compositional layering S that can be identified in isolated microlithons. Chlorite is locally observed to form at the expense of biotite and grows in the main foliation, implying that this fabric formed at greenschist-facies conditions. In combination, these observations suggest that peak-metamorphic conditions in the spotted schists were attained before the D3 event that locally forms the penetrative fabrics observed. This would be in support of our hypothesis portrayed in cross sections (Fig. 3-5 and 6), according to which the nappe structure within the Yuli Belt was refolded during D3.

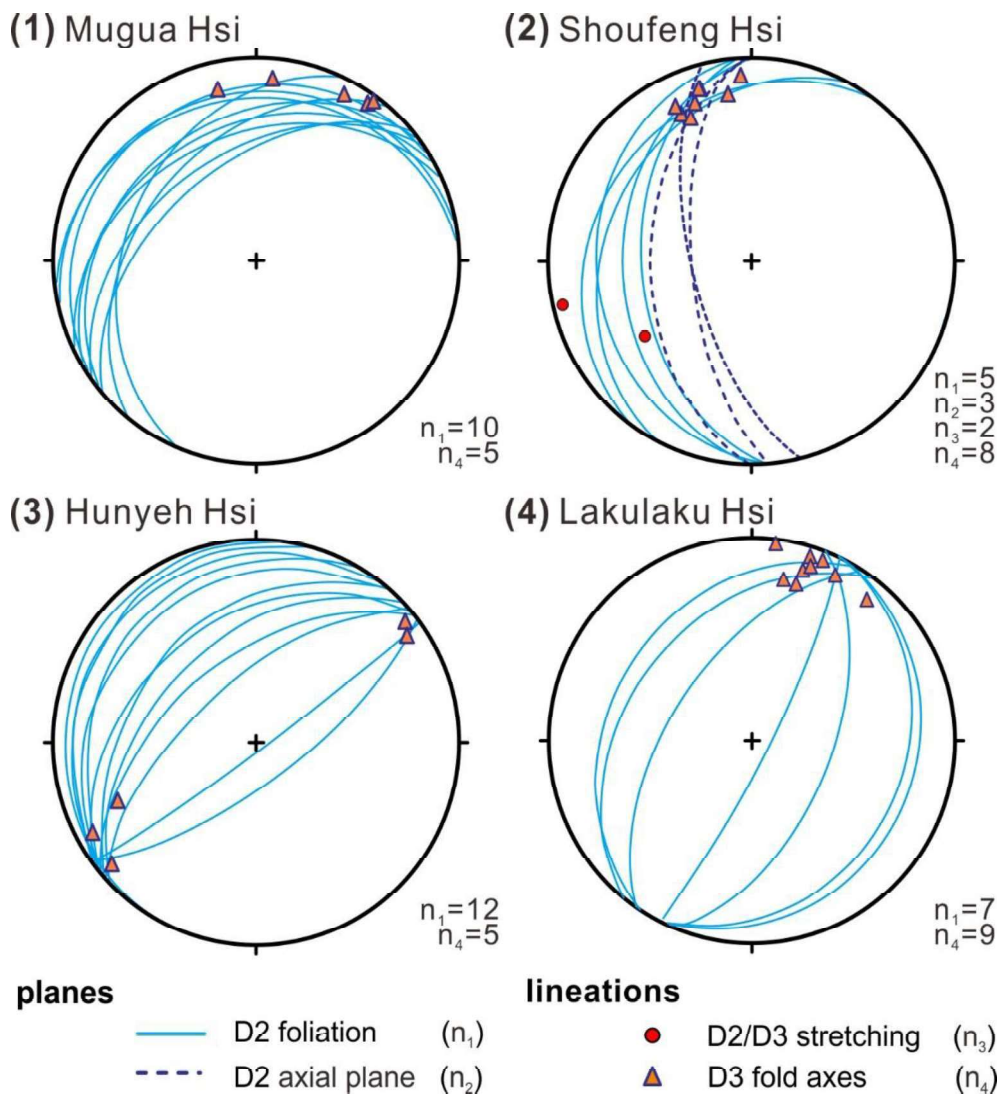

Fig. 3-8: Equal area, lower hemisphere ("Schmidt net") projections of fabric elements across Yuli Belt (1-4) considered representative for the map-scale structures. Compare with Fig. 3-7 for actual outcrop geometries at the corresponding locations. (1)-(a) Mugua Hsi; (2)-(i) Shoufeng Hsi (23.841331°N, 121.380597°E); (3)-(b) Hunyeh Hsi; (4)-(d) Lakulaku Hsi.

Fig. 3-9: Microscopic features of albite spotted mica schists from the Hunyeh Hsi and Xinwuliu Hsi areas of the Yuli Belt, respectively. (g)-1 and (h)-1 are in plane-polarized light; (g)-2 and (h)-2 in cross-polarized light. (g): albite-chlorite-mica schists in the Hunyeh Hsi area of Fig. 3-7b with pressure solution cleavage affecting an asymmetric albite σ -porphyroclast in metapelites. (h): albite-quartz-mica schists from the Xinwuliu Hsi area of Fig. 3-7e, showing mylonitic foliations with top-to-SE sense of shear during D3. Abbreviations: Ab = albite; C = carbonaceous material; Chl = chlorite; Qz = quartz; Ti = titanite; Wm = white mica.

3.4 Whole-rock geochemistry of the HP metamorphic rocks

3.4.1 Sampling and petrography

Twelve rock samples were collected for this study from three tectonic high pressure metamorphic blocks of Yuli Belt, i.e., Wanjun, Juisui, and Chinsui Hsi areas (Table 3-3; Fig. 3-4; see Appendix B- Fig. S2 for sample localities), to further extend the sample base (e.g., Liou et al. 1975; Jahn et al. 1981; Lin et al. 1984; Sun et al. 1998; Shao 2015) for characterizing geotectonic settings in which they were issued. Most of samples are from the largest tectonic block, Juisui / Tamayan area (e.g., Fig. 3-10(A)); two samples are from Wanjun area (e.g., Fig. 3-11(c)); and one sample is from Chinsui Hsi area (Fig. 3-11(b)).

The rock samples can be classified into five groups according to mineralogical and petrographic studies (e.g., Liou et al. 1975 and this study; Fig. 3-12). In some cases, garnet-rich coarse-grained dark amphibolite are in direct contact with garnet free fine-grained amphibolite (Fig. 3-11(a), Fig. 3-10(C)). Pillow structures are preserved in the massive to foliated amphibolite (Fig. 3-10(B)). (1) Glaucophane schists: Glaucophane-bearing rocks (Type I and Type II after Tsai et al. 2013) occur as layers or irregular meter-scale boulders surrounded by greenschist or amphibolite. Major phases are amphibole (42%), quartz (24%), epidote (21%) and garnet (11%). In these rocks, glaucophane occurs only as rare inclusions within porphyroblastic bluish-green amphibole (Fig. 3-11(g)). (2) Garnet-epidote amphibolites (Type III in Tsai et al. 2013): Major phases are amphiboles (40%), epidote (19%), garnet (12%), and quartz + albite (27%). Garnet is euhedral and zoned. Quartz, epidote, and rare dolomite are present in garnet cores (Fig. 3-11(e), (f)). (3) Epidote amphibolites (glaucophane free Type IV in Tsai et al. 2013): Garnet-absent rocks with major phases of amphiboles (45%), epidote (24%), paragonite (10%), and quartz + albite (18%). (4) Chlorite schists: They were collected from Wanjun area (Fig. 3-11(c), (d)). Major phases are chlorite (45%), albite (40%), amphiboles (6%), epidote (5%), and titanite (1%). (5) Meta-albite rich felsic / albitite rocks: They were collected from Chinsui Hsi area (Fig. 3-11(b), (h)). The albitite consist of euhedral porphyroblastic albite (85%), amphiboles (6%), white mica (3%). They occur as irregular masses or layers surrounded by serpentinite or talc albite chlorite schists (Fig. 3-10(F)).

3.4.2 Analytical methods

After removing weathered surfaces, all samples were crushed in a jaw-crusher, cleaned in an ultrasonic bath with deionized water, sieved and carefully hand-picked under a binocular microscope to avoid the most altered portions of the samples. Selected whole rock chips (~10g) of each sample were ground with a ball mill (sintered corundum) to a grain size < 63 µm for homogenization and dried at 105°C overnight. Major elements (Table 3-3) were measured using

X-ray fluorescence (XRF) and after total digestion, selected trace elements (Table 3-4) were measured using inductively coupled plasma-optical emission spectrometry (ICP-OES) and inductively coupled plasma-mass spectrometry (ICP-MS) at the Institute of Geological Sciences at the Friedrich-Schiller University Jena.

Fig. 3-10: Field occurrences of the high-pressure metamorphic rocks from Yuli Belt. (A)-(C): A slump float in Hungyehhsi/Juisui area. Garnet-free and garnet-rich mafic amphibolite with flattened pillow structures. The medial boundary zone is enriched in coarse-grained, dark-green calcic amphibole and fine-grained yellowish epidote as thin folded layers. (D): Unmetamorphosed Pillow basalts from Taitung (Lin et al. 2019) for comparison. (E): The contact relationships between chlorite talc schists, chlorite albite schists, and carbonaceous (C) -rich pelitic schists from a serpentinite pit mine, Chinsuihsi area. (F): Actinolite (Act) and albitite are included in albite chlorite schists and carbonaceous (C) -rich pelitic schists from Chinsuihsi area.

Fig. 3-11: Megascopic and microscopic features of the high-pressure metamorphic rocks from Yuli Belt. The coin is 23.25 mm in diameter for scale in (a) and (b). (d), (e) and (f) are photomicrographs in cross polarized light. (g) and (h) are photomicrographs in plan polarized light. (a): Hand specimen of a garnet-hornblende metagabbro from Juisui area. It is subdivided into the fine-grained amphibolite type (YQ17-50a) and the coarse-grained amphibolite type (YQ17-50b). (b): Hand specimen of an amphibole albite schist from Chisuihsi area (YQ17-30). (c): Southwest-dipping foliated and banded amphibole-rich chlorite schists at the mountain path of Wanjung (23°42'38.10"N, 121°24'37.49"E). (d): epidote-clinozoisite-chlorite-amphibole-albite schists from the sample area of (c). (e), (f) and (g) are garnet-epidote-amphibole gneiss/schists from Juisui area. (h): Thin section of sample (b). Abbreviations: Ab=albite; Amp=amphibole; Czo=clinozoisite; Chl=chlorite; Ep=epidote; Grt=garnet; Wm=white mica; Pl=plagioclase; Qz=quartz; Rt=rutile.

3.4.3 Major element compositions

Major element data for sixteen samples from three high-pressure metamorphic units are given in Table 3-3. The analyzed rocks show a wide compositional range on the total alkali-silica (TAS) diagram (Fig. 3-12). The SiO_2 content ranges from 42 to 66 wt.% with a small gap between 59 and 63 wt.% (Bunsen-Daly gap; Bunsen, 1851; Daly, 1925; Bonnefoi et al., 1995), and the $\text{Na}_2\text{O} + \text{K}_2\text{O}$ ranges from 0.5 to 10.5 wt.%, dividing the samples into mafic (mostly $\text{MgO} = 2.8\text{-}13.0$ wt.%) and felsic (mostly $\text{MgO} = 1.50\text{-}6.20$ wt.%) suites (Table 3-3). Most of meta-mafic rocks (Group (1)-(4)) are in the subalkaline/ tholeiite series, and meta-felsic rocks (Group (5)) are plotted in the alkaline series (Fig. 3-12). Chlorite schists (4) and albitite rocks (5) have lower K_2O (< 0.30 wt%) and higher Na_2O (> 8 wt%).

Fig. 3-12: TAS diagram $\text{SiO}_2/(\text{Na}_2\text{O} + \text{K}_2\text{O})$ of Le Bas et al (1986). Samples are divided into five groups: (1) Glaucophane schists; (2) Garnet-epidote amphibolites; (3) Epidote amphibolites; (4) Chlorite schists; (5) Meta-albite rich felsic / albitite rock. Data from Liou et al. (1975), Jahn et al. (1981), Lin (1984), Sun et al. (1998) and Shao (2015) are included for comparison.

Table 3-3: Concentrations of the major element oxides of the high pressure metamorphic rocks from the Yuli Belt, Taiwan (wt.%). Major elements were measured using X-ray fluorescence (XRF). < LOD: below the limit of detection. LOI: Loss on ignition. See Appendix B- Fig. S2 for sample localities.

Sample name	Lithology	Location	SiO ₂	Al ₂ O ₃	TiO ₂	CaO	K ₂ O	Na ₂ O	Fe ₂ O ₃	MgO	MnO	P ₂ O ₅	Total	LOI

Fig. 3-13: Plots of MgO versus other major oxides (Harker diagrams). Data from Liou et al. (1975), Jahn et al. (1981), Lin (1984), Sun et al. (1998) and Shao (2015) are included for comparison. Grey arrows roughly indicate the trends from mafic suites (Group-4) and (3) to felsic suites (Group-5).

Plots of MgO versus other major oxides are shown in Fig. 3-13. Both glaucophane schists (1) and garnet-epidote amphibolites (2) with distinctly higher MnO (> 0.50 wt%), higher P_2O_5 (> 0.15 wt%) and lower Na_2O (< 2.20 wt%) have apparently accumulated larger grain size of garnet consistent with petrographic examinations (Fig. 3-11 (e)(f)(g); Fig. 3-13). Garnet-epidote amphibolites (2) also have pronouncedly higher CaO (> 12 wt%) and lower Al_2O_3 (< 13 wt%). The MnO and P_2O_5 content of epidote amphibolites (3) are lower than other mafic rock types (MnO = ca. 0.1-0.2 wt% and P_2O_5 = ca. 0.1 wt%) while the Na_2O and Al_2O_3 content are higher (Na_2O = ca. 2-8 wt% and Al_2O_3 = ca. 14-18 wt%). The chlorite schists (4) are scattering plotted in the $SiO_2 / (Na_2O + K_2O)$ diagram with a large range of SiO_2 (ca. 43-58 wt%) and MgO (ca. 3.5-16 wt%) content. In most cases, chlorite schists (4) points are seated in the area of epidote amphibolites (3) (Fig. 3-13), indicating both of rocks could share similar

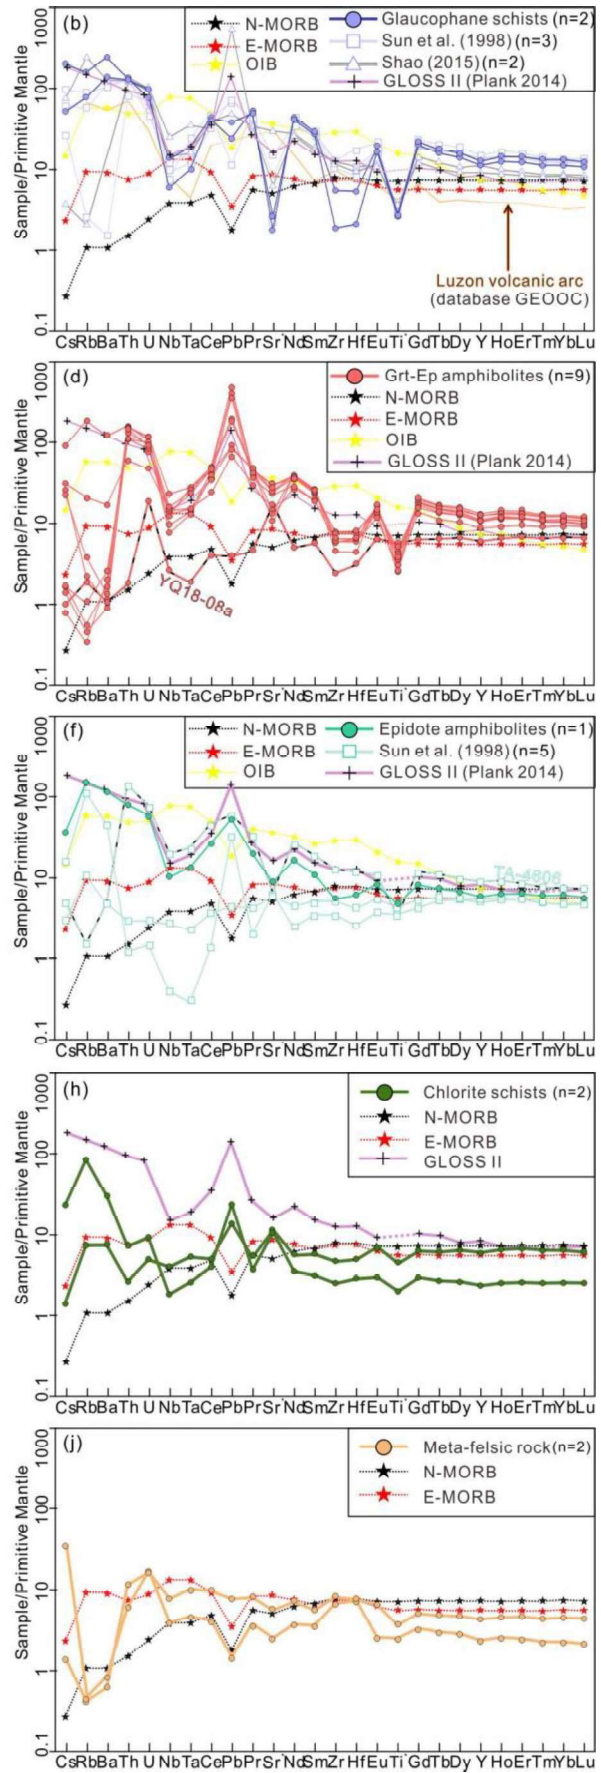

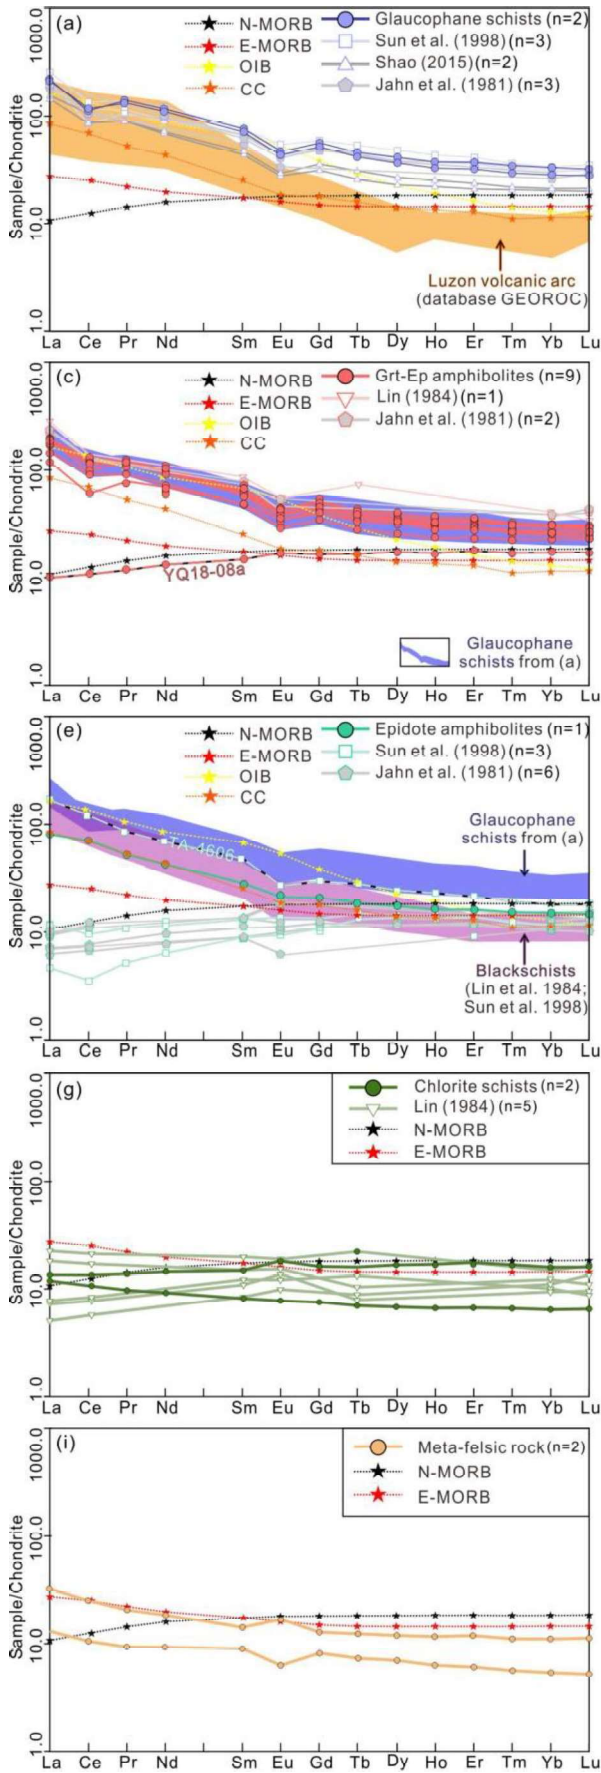

Fig. 3-14: Chondrite-normalized REE patterns are on the left side. Data are normalized to chondrite of Sun and McDonough (1989). Primitive mantle-normalized trace element multivariation diagrams are on the right side. Data are normalized to primitive mantle of Hofmann (1988). Sr* and Ti* are measurements of OES. The REE patterns of Blackschiefs are after Lin et al. (1984) and Sun et al. (1998). Global subducted sediments (GLOSS II) are after Plank (2014). The database GEOROC (Geochemistry of Rocks of the Oceans and Continents) of Luzon volcanic arc is from <http://georoc.mpch-mainz.gwdg.de/georoc/>. Trace elements data of the normal mid-ocean-ridge basalt (N-MORB), enriched mid-ocean-ridge basalt (E-MORB), oceanic-island basalt (IOB) are after Sun and McDonough (1989). Chondrite-normalized REE patterns of the continental crust (CC) are after Rudnick and Gao (2003). Yuli Belt trace elements data from Liou et al. (1975), Jahn et al. (1981), Lin (1984), Sun et al. (1998) and Shao (2015) are included for comparison. (a) and (b): Group (1), Glaucofane schists. (c) and (d): Group (2), Garnet-epidote amphibolites. (e) and (f): Group (3), Epidote amphibolites. (g) and (h): Group (4), Chlorite schists. (i) and (j): Group (5), Meta-albite rich felsic / albitite rocks. High-res images are enclosed in the supplement.

characteristics in major elements. Albitite rocks (5) have high (Na₂O + K₂O) as well as SiO₂ and plot in the trachydacite field (Figs. 3-12, 3-13).

3.4.4 REE and trace element compositions

The trace element data (Table 3-4 and Figs. 3-14, 3-15) show that the analysed metamorphosed samples display distinct rare earth element (REE) patterns and trace element multivariation diagrams (spider diagrams). On the Zr/4-2Nb-Y discrimination diagram (Meschede 1986) and Ti-V discrimination diagram (Shervais 1982) (Fig. 3-15), most of our samples plot both within or above the normal mid-ocean-ridge basalt (N-MORB) to back-arc basin (BAAB) array. Below, we will present and discuss the trace element in five groups, the same classification with major element compositions (Fig. 3-12).

Group (1): Glaucofane schists

Glaucofane schists samples display the lower ratio of La/Yb than the Luzon volcanic arc, although the glaucofane schists show similar light rare earth element (LREE) trends with the Luzon volcanic arc. Glaucofane schists have more enriched heavy rare earth element (HREE) above MORB values than the Luzon volcanic arc (in the yellowish background) (Fig. 3-14(a)).

Group (2): Garnet-epidote amphibolites

A suite of trace elements including Th, U, Nb, Ta, Zr, Hf, and the REE shows approximately equal concentrations in the glaucofane schists and garnet-epidote amphibolites (Fig. 3-14 (a)-(d)). A slightly negative Europium (Eu) anomaly ($Eu/Eu^* = \text{avg. } 0.25$; $Eu^* = \sqrt{Sm \times Nd}$) relative to the other REEs might indicate plagioclase is a residual solid in a reducing magma, where Eu²⁺ substitutes for calcium (Ca²⁺) (Fig. 3-14(a)(c)) in shallow (< 40 km) partial melting of the mantle (e.g., Weill and Drake 1973). The spider diagrams of the glaucofane schists and garnet-epidote amphibolites show a similar pattern (Fig. 3-14(b)(d)) and, except for some mobile elements such as Cs, Rb, and Ba, as well as the usually immobile Sr, have similar values.

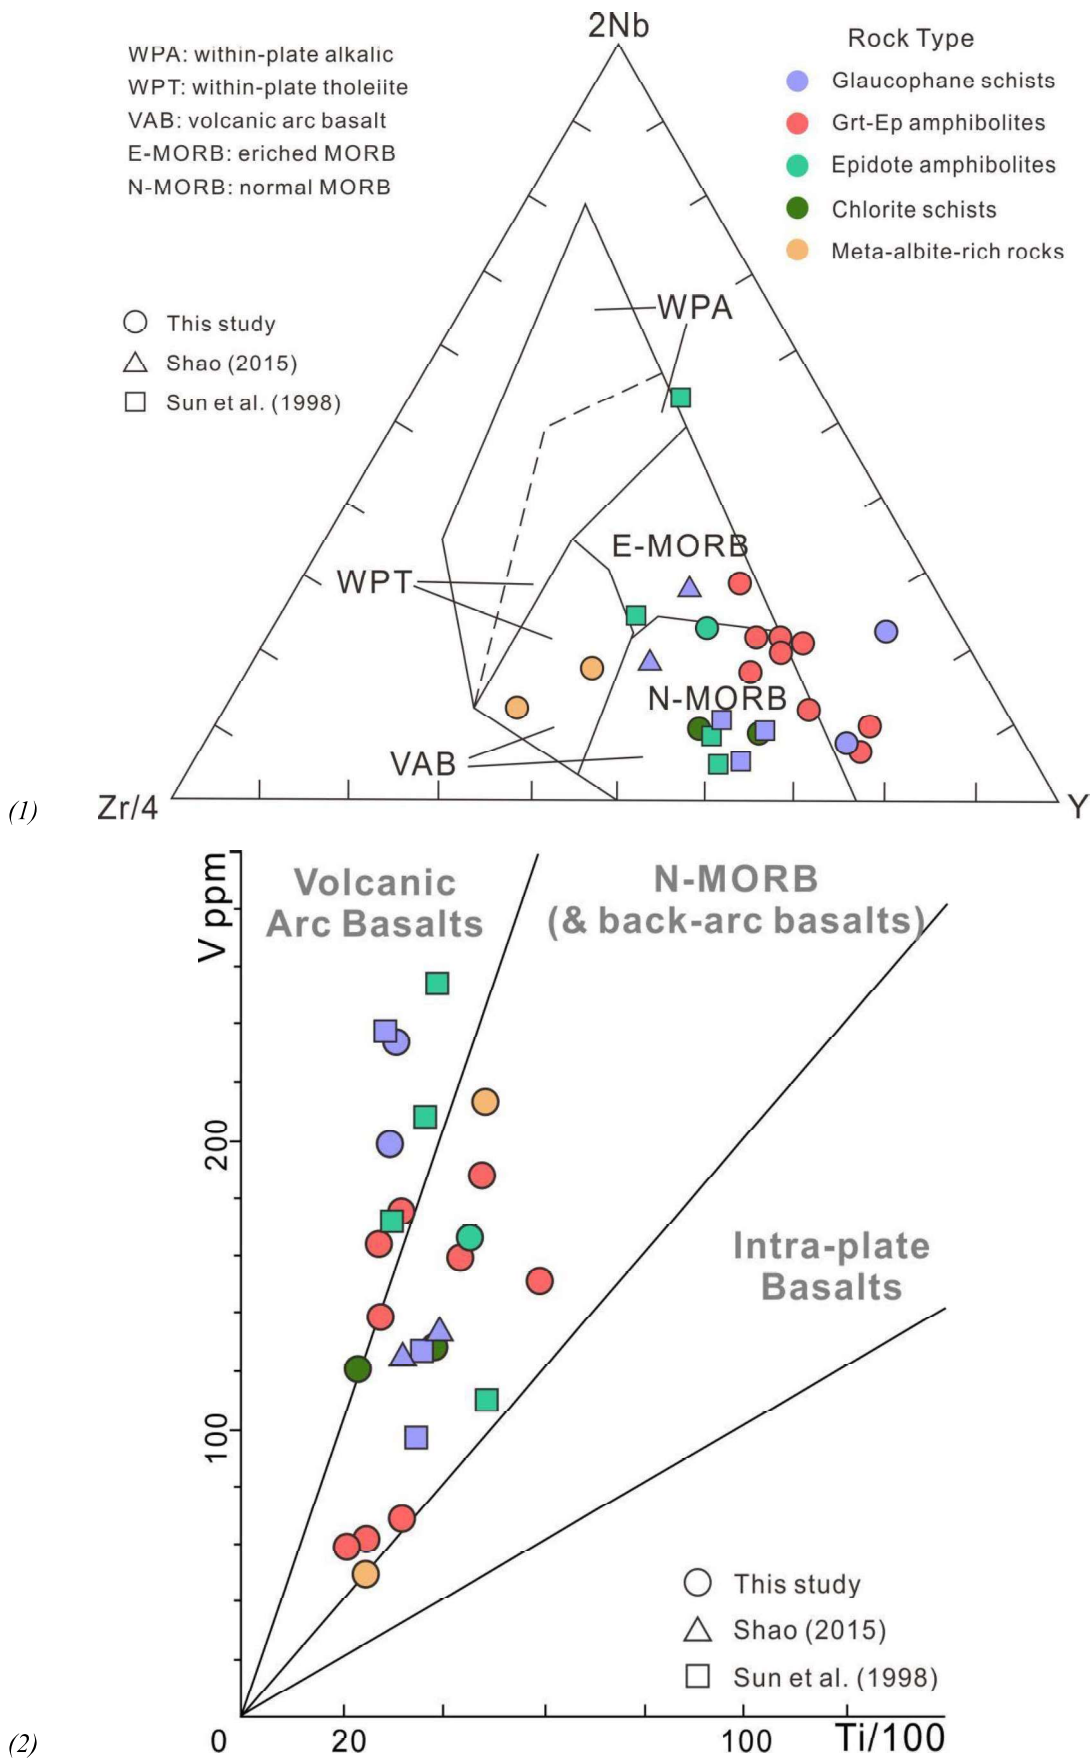

Fig. 3-15: (1) The Zr/4-2Nb-Y discrimination diagram after Meschede (1986). (2) Ti-V discrimination diagrams (Shervais, 1982) for Yuli Belt rocks of this study. Symbols as in (1). Data from Sun et al. (1998) and Shao (2015) are included for comparison.

One exception of sample YQ18-08a in the garnet-epidote amphibolites group, shows a similar REE pattern with N-MORB in Fig. 3-13(e) and is characterized by low concentrations of Nb - Ta, a typical signature of subduction-related melts (Pearce, 1982). Besides, the Zr-Hf trough in both glaucophane schists and garnet-epidote amphibolites groups may indicate a melt that assimilated continental crust. Therefore, it is an indication for supra-subduction environments.

Group (3): Epidote amphibolites

Garnet concentrates the HREE and fractionates. Both glaucophane schists and garnet-epidote amphibolites display higher HREE above MORB values than epidote amphibolites (Fig. 3-14(a)(c)(e)). Most of epidote amphibolites are characterized by relatively flat HREE patterns, similar to N-MORB. Variably elevated abundances for large-ion lithophile element (LILE) and Pb relative to N-MORB could be due to the seawater hydrothermal alteration and the crustal contamination. Two exceptions of TA-4606 (Sun et al. 1998) and our sample UK 09-24 displaying the LREE enrichment and HREE depletion relative to MORB values, indicate an igneous signature, with Ta-Nb depletion in a supra-subduction environment. However, the two samples with relatively negative Eu anomaly exhibit chemical compositions similar to blackschists in the Yuli Belt and global subducted seafloor sediments (GLOSS II) (Lin et al. 1984, Sun et al. 1998, Plank 2014; Fig. 3-14 (e)(f)), considered to be strongly contaminated by an aqueous environment.

Group (4): Chlorite schists

These REE data collectively indicate that the geochemical composition of chlorite schists is similar to that of typical MORBs of the South China Sea (Fig. 3-14 (g)). However, significant enrichment in LILE, Pb, LREE, Nb and Ta relative to N-MORB despite the Nb-Ta trough in the diagram (Fig. 3-14 (h)) show chlorite schists have been influenced by hydrogenetic or hydrothermal components during subduction.

Group (5): Meta-albite rich felsic / albitite rocks

Two meta-albite rich felsic/albitite rocks with LREE enrichment support for the origin of E-MORB from the South China Sea (Figs. 3-14 (i)(j), 3-15(2)). These samples show both positive and negative Eu anomalies as actual MORB melts (e.g., Niu and O'Hara 2009). Primitive mantle normalized incompatible element distribution patterns of two samples exhibit negative anomalies in Rb, Ba and positive anomalies for Th, U (Fig. 3-14 (j)), with an indication for a fluid imprint.

3.4 Discussions

3.4.1 Structural position of the Yuli Belt high-pressure blocks

By correlating outcrop-scale observations with cross sections, we interpreted the high-pressure metamorphosed blocks to form allochthonous nappe outliers (or erosional relics) of a formerly more contiguous thrust sheet, which emplaced subducted and exhumed portions of crust and mantle on top of the lower-grade metasedimentary unit (Fig. 3-5 and 3-6). In the following, we term this fault “Juihsi Thrust” after the locality with the largest exposures of blueschist-facies rocks (Fig. 3-5). Nappe emplacement must have occurred after peak-P-T conditions in the high-pressure unit have been reached. This interpretation is supported by contrasting P-T-conditions in the blueschist-facies and the metasedimentary units (Appendix B- Fig. S1). Peak pressures and temperatures obtained for the high-pressure unit (c. 1.0 to 1.7 GPa and 500-550°C, respectively; Beyssac et al. 2008; Tsai et al., 2013; Sandmann et al. 2015; Keyser et al., 2016; Baziotis et al., 2017; Lo 2018; Appendix B- Fig. S1) are higher than those of the metasedimentary unit (0.9 GPa; Chiang 2003), although more recent work suggests substantially higher pressures, but lower temperatures for the metasediments (up to 1.5 GPa and 330-400°C; Conand et al. 2020). These contrasting P-T-conditions nourish our assumption of two tectonic units that require to be separated by a thrust. The juxtaposition of high-pressure blueschist unit and metasedimentary unit along this thrust occurred very likely during D1 or early D2; certainly before the refolding of all units during D3 and likely concomitant with late-stage retrogression at greenschist facies conditions below c. 3 kbar and 370 °C (Appendix B- Fig. S1; Fig. 3-14). This is in agreement with our cross sections with the west-dipping axial planes formed during D3 (Fig. 3-5,6,8b). D3 refolding and back-thrusting, in combination with later erosion, was responsible for the separation of high-pressure rock occurrences in map view. For the sake of completeness, we mention that the idea of the existence of such thrusts was first proposed by Yang and Wang (1985).

3.4.2 Palaeogeographic origin of the Yuli Belt and a kinematic evolutionary scheme

From geochemical considerations it has been concluded that the Yuli belt high-pressure metamorphic rock assemblage exhibits the features expected in the MORB-like basalt of the South China Sea (e.g., Group (2)YQ18-08a, Group (3), (4), and (5)), and could display the effects of metasomatism of their mantle source by slab-derived fluids and alteration from low-temperature seafloor in the subduction zone (e.g., Group (1), (2)), which are varied in LILE (e.g., Rb, Ba, and Sr) and depleted in high field strength elements (HFSE) (e.g., Nb, Ta, and Ti). Although all samples are metamorphic rock, the maximum metamorphic depth are less than 60 km (Appendix B- Fig. S1). In this depth, the equilibrium partitioning between the

metamorphic minerals is generally inhibited and the metamorphic minerals should persist the original composition of protolith (Spandler et al. 2003). Therefore, we consider the dominantly mafic to ultramafic and subordinately metasedimentary blueschist-facies tectonic blocks of the Yuli Belt to have been derived from the oceanic crust of the South China Sea. This interpretation is based on a number of arguments outlined in the following. We minted our arguments into a

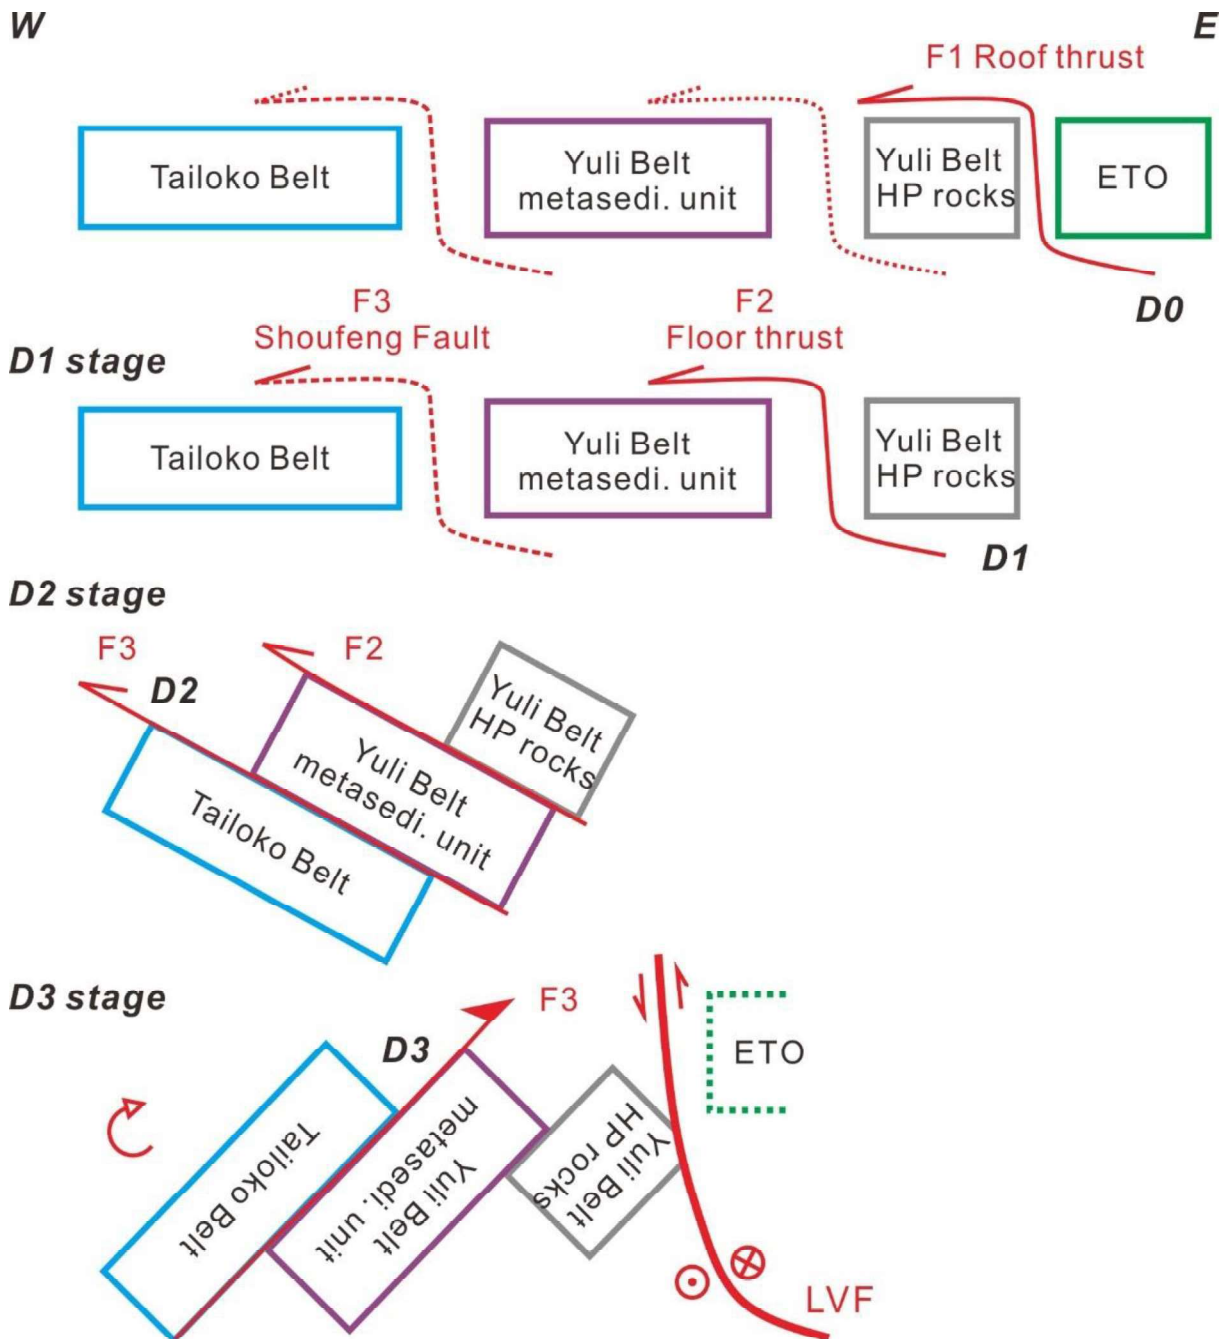

Fig. 3-16: A kinematic evolutionary “shoe box” cartoon illustrating deformation stages, starting with the suspected paleogeographic configuration. D0 stage: the subduction of the Yuli Belt HP unit along the roof thrust; D1 stage: HP metamorphic rock thrust over the Yuli Belt metasedimentary unit along the floor thrust; D2 stage: W-ward thrusting of Yuli Belt onto Tailoko Belt along Shoufeng Fault; D3 stage: backfolding and inversion of slip sense on Shoufeng Fault.

new kinematic evolutionary three-stage scheme for the Yuli Belt (Figs. 3-16, 3-17) and into a palaeogeographic sketch of the South China Sea and the Philippine Sea for 15 Ma (Figs. 3-17, 3-18). We selected the GPlates framework of a global plate reconstruction of Wu and Suppe (2018) using a hybrid absolute reference frame that includes moving Indian/Atlantic hotspots and a true polar wander corrected paleomagnetic-based model (O'Neill et al. 2005; Seton et al. 2012), and projected the present-day as well as the 15 Ma palaeogeographic reconstructions.

(1) Available protolith ages for the blueschists, constrained from U-Pb LA-ICP-MS dating of zircons, are around 15.4–16.0 Ma (Chen et al. 2017; Lo et al. 2020), making them well comparable in age with gabbros from the easterly adjacent, unmetamorphosed ETO accreted to the base of the Lichi Mélange (Hsieh et al. 2017; Lin et al. 2019; Huang et al. 2018; Table 3-1, Table 3-2 and Fig. 3-2, 3-10(B)(D)). These ages are about the youngest possible for oceanic crust issued at a mid-oceanic ridge of the South China Sea (Table 3-1), which ceased spreading at about 15.5 Ma (see Section 3.2 and Fig. 3-2). The geochemical composition of basalts and gabbros in the ETO has affinities towards MORB and/or BABB (Lin et al. 2019). Based on these geochemical data and ages, we conjecture that the most probable locus, where both the Yuli Belt blueschists and the ETO originated, was to either side of a spreading ridge of the South China Sea (Fig. 3-16a). We took this idea further by positioning the original locus of these units on a simple palaeogeographic reconstruction for 15 Ma (Fig. 3-18). Assuming that both the present-day plate convergence rate of 7-8 cm/a (Seno, 1977; Yu et al. 1997) and the NW-SE-oriented convergence direction between Eurasian and Philippine Sea plates (after Seno, 1977) were constant during the last 15 Ma, we roughly aligned the possible original palaeogeographic locations of both Yuli Belt and ETO on three positions along this trajectory (red and blue dashed stars in Fig. 3-18b). Given large uncertainties on the trend of the subducted portions of the spreading ridges (cross-hatched area in Fig. 3-18b), all three pairs of stars mark positions where South China Sea oceanic crust might have formed near a mid-oceanic ridge at c. 15 Ma. However, only the southeasternmost pair of red and blue dashed stars is in good agreement also with the amount of plate convergence that has occurred since 15 Ma, amounting to roughly 1100 km using the simple assumptions above. This “preferred” position is conspicuously close to the position of the Manila trench reconstructed by Lee and Lawer (1995; blue line in Fig. 3-18b), which we hence prefer over the two alternative reconstructions of Sibuet et al. (2002; green line in Fig. 3-18b) and Wu and Suppe (2018; red line in Fig. 3-18b), which would only be viable if substantially slower convergence rates operated, which, in turn, is considered unlikely (Wu and Suppe, 2018).

Fig. 3-17: Lithosphere-scale kinematic model to explain the origin of the Yuli Belt of Taiwan. The Yuli Belt is interpreted to have originated from a subducted and exhumed segment of the South China Sea, relying on time constraints from Chen et al. (2017) and Lin et al. (2019) for igneous protolith ages in the Yuli Belt and East Taiwan Ophiolites, respectively. See text for further discussion.

In our kinematic evolutionary sketch (Fig. 3-17), we show an intraoceanic subduction zone already operating at 15 Ma. This takes account of (i) the oldest reported ages for subduction-related magmatism in the Coastal Range dating back to the Late Oligocene (Table 3-1), (ii) maximum stratigraphic age constraints of the Tuluanshan Fm. in the Coastal Range (Fig. 3-2) as well as (iii) plate tectonic reconstructions for 15 Ma as discussed above, which show the Manila Trench at variable longitudes in the western Philippine Sea (Lee and Lawer, 1995; Sibuet et al., 2002; Wu and Suppe, 2018; Fig. 3-18b).

(2) Subduction of the oceanic crust and lithosphere forming the Yuli Belt blueschists must have commenced soon after ~15 Ma (e.g., Jahn et al. 1981; Lo and Yui, 1996), with peak metamorphic conditions reached between 15 and 10 Ma (Chen et al., 2017). At the same time, the ETO has escaped the fate of being subducted, implying that it must have been frontally accreted to the wedge forming along the Manila trench (Fig. 3-18b). We suspect that the metasedimentary unit of the Yuli Belt, with depositional ages inferred to be as young as mid-Miocene (Chen et al. 2017; Figs. 3-2 and 3), occupied a more continent-ward paleogeographic position prior to its subduction (Fig. 3-11a). Despite the absence of any geochronological data on metamorphic conditions from this unit, we further suspect that it must have closely followed the blueschist unit into subduction (Fig. 3-17b; Appendix B- Fig. S1).

(3) Exhumation of the Yuli Belt series was facilitated by the failure of the upper plate along a lithosphere-scale fault forming between the dense, negatively buoyant fore-arc lithosphere and the more buoyant magmatic Luzon arc upon the entrance of Eurasian continental lithosphere in the trench between c. 6 and 4 Ma (Chemenda et al. 2001). Subsequently, ongoing convergence led to subduction of the negatively buoyant fore-arc lithosphere by slab extraction (Froitzheim et al. 2003; Shyu et al. 2011; Sandmann et al. 2015; Fig. 3-17c), a mechanism that very efficiently reduced the overburden on top of the subducted material. We conjecture (i) that this mechanism of slab extraction was at play both for the blueschist-facies units as well as for the metasedimentary unit of the Yuli Belt and (ii) that the juxtaposition of these units along the floor thrust occurred during this stage (Fig. 3-16). Roof and floor thrust of the blueschist-facies unit define part of the suture zone between Eurasian and Philippine Sea Plates, and they likely formed during this stage of fore-arc subduction. We suggest that the easterly adjacent ETO (from which the Yuli Belt is presently separated by the LVF), should be considered to constitute the remainder of Taiwan's suture zone. Such an assembly with blueschist-facies oceanic units overlain by unmetamorphosed oceanic units is also described from the Chenaillet Ophiolite in the French-Italian Western Alps, where it is attributed to represent the suture between European and Adriatic units (e.g., Manatschal et al., 2011). Furthermore, we suspect that the juxtaposition

of the Yuli Belt series and Tailuko belt along the Shoufeng Fault could have occurred within this timespan.

Finally, we realize that it is increasingly difficult to reconcile the Lu-Hf isochron ages of 5.1 ± 1.7 Ma, considered to reflect peak-pressure conditions during blueschist-facies metamorphism (Sandmann et al. 2015) with the fact that between about 6 to 4 Ma continental lithosphere of Eurasia has entered the subduction, dating the transition from intra-oceanic subduction to continent-arc collision (Chi et al. 1981; Suppe 1984a; Fig. 3-17c). The even younger U-Pb ages on zircon rims from nephrite at Fengtien (3.3 ± 1.7 Ma; Yui et al. 2014), however, may still be geologically viable, as this method possibly dates peak-temperature conditions rather than peak-pressures. In this case, Yui et al. (2014) would have likely obtained an age at which post-collisional shortening during deformation phase D3 was at work. We conclude that further geochronological and structural work is hence needed to better constrain the timing of peak-metamorphic conditions and their structural imprint on the Taiwan orogen.

3.5 Conclusions

Three new cross-sections across Taiwan's Yuli Belt were constructed, taking new outcrop- to microscope-scale structural observations from several river-transects into account. Our observations suggest that the Yuli Belt was affected by at least three successive deformation phases (D1 to D3). We suspect that high-pressure metamorphic units were emplaced on top of metasedimentary units of Yuli Belt along a thrust during D1. This assembly was later thrust over Eurasian-derived series of the Tailuko Belt along the Shoufeng Fault during D2, suggested by (rarely preserved) downplunging stretching lineations on W- to NW-dipping foliation planes. E-vergent open to tight folds throughout the Yuli Belt with W- to NW-dipping axial planes were produced by the D3 phase, refolding earlier foliations as well as the D1 nappe contact, during which also the blueschist-facies and metasedimentary units were folded. This phase might be related to a top-E back-thrusting and a reorientation of the Shoufeng Fault from an initially E-dipping to a presently W-dipping contact, for which we present new evidence. We interpret the high-pressure metamorphic units to form erosional relics of nappe outliers of a formerly more contiguous thrust nappe that hosts part of the suture zone in Taiwan. The whole-rock geochemical fingerprint of high-pressure metamorphic rocks is in the MORB tectonic settings. Therefore, we suggest that the blueschist-facies metamorphic unit most likely represents a mid-Miocene fragment of oceanic crust and mantle issued in the South China Sea before having been subducted, exhumed and 'sandwiched' between the Tailuko Belt and the easterly adjacent Coastal Range derived from the Philippine Sea Plate.

Fig. 3-18: a: Present-day plate tectonic map around Taiwan. b: Paleogeographic reconstruction for 15 Ma showing possible locations of the Yuli Belt (red star) and East Taiwan Ophiolite (blue star), the eastward-extension of the spreading ridge of the (now subducted) South China Sea as well as proposed positions of the Manila Trench at 15 Ma according to Lee and Lawer (1995), Sibuet et al. (2002) and Wu and Suppe (2018). Uncertainties in the position of the now subducted spreading ridge (checkered area) arise from the eastward projection of the azimuthal range of magnetic anomalies below the present-day position of the Manila Trench. Assuming a constant plate convergence velocity and the spreading ridge subducted beneath the Manila Trench is confirmed from seismic tomography (Yeh et al. 2012; Wu and Suppe 2018). The former continent-ocean boundary (COB) is reconstructed on the basis of shortening estimates of the three transects (Chapter 2). High-res images are enclosed in the supplement.

Chapter 4

Thermal evolution of the metamorphism in the eastern Taiwan: implications for blueschist exhumation

This manuscript is in preparation for submission.

Abstract:

The Yuli Belt in Taiwan's eastern Central Range encloses high pressure (HP) mafic-ultramafic blocks in intensely deformed greenschist-facies metasediments. It is still debated how its structures relate to those of the westerly and easterly adjacent units. We integrated new and published Raman-spectroscopic measurements on carbonaceous matter from metasedimentary successions across the Tailuko and Yuli Belts and combined these results with new cross sections. Our results suggest temperature variations of up to 150°C within the Yuli Belt itself, with lower temperatures between 400 and c. 460°C within the metasediments and up to 550° in spotted schists directly underlying the HP metamafic assemblages. No temperature gradient can be found across the Shoufeng Fault separating the Yuli and Tailuko belts in the west. The most pronounced temperature gradient exists across a fault contact between the Yuli Belt and the easterly adjacent Chulai Fm. Both Chulai Fm. and Backbone Slates to the west of the Tailuko Belt exhibit $T < 400^{\circ}\text{C}$. In combination with lithological similarities, we consider the Chulai Fm. an easternmost extension of the Backbone Slates. We suggest that the Yuli Belt was initially emplaced on top of lower-grade Paleogene successions. Later, the nappe succession was overprinted by E-vergent backfolding of the Central Range and contemporaneous backthrusting along the Shoufeng Fault, leading to the presently observed synformal structure of the Yuli Belt.

Keywords: Taiwan; Yuli Belt; geothermometer; RSCM; blueschists

Statement of significance:

Unlike the Alps and the Himalaya, where topographic growth occurred well-after the onset of submarine continental accretion, Taiwan is characterized by a much shorter time interval between these two tectonic stages. This makes the interpretation of pressure-temperature-timing data challenging. A careful inspection of metamorphic temperature trends in sedimentary successions is thus particularly important. Our results support the effectiveness of Raman spectroscopy for carbonaceous material as geothermometer for deformed greenschist-facies metasediments to provide peak metamorphic temperatures in the eastern Taiwan Central Range that are useful to constrain deformation phases.

4.1 Introduction and geological setting

The collision between the Eurasian passive continental margin and the Luzon volcanic arc of the overriding Philippine Sea Plate formed the Taiwan Central Range since ca. 4–6 Ma (e.g., Chang and Chi, 1983; Suppe, 1984a). Five roughly N-S oriented major morphotectonic units make up the Taiwan mountain belt (Fig. 4-1a). The Longitudinal Valley Fault (F4) separates units to the west derived from the Eurasian Plate, and the Coastal Range of the Philippine Sea Plate to the east. The Backbone Slates comprises a metamorphosed Cenozoic sedimentary cover unconformably overlying the Mesozoic metamorphic basement (the Tailuko Belt of the Tananao Complex) (Fig. 4-1a). The outcropping stratigraphy of the Backbone Slates consists of the prehnite–pumpellyite to greenschist facies Pilushan phyllite (incl. Heiyenshan and Tayuling formations) of Eocene (to Miocene) age as well as the prehnite–pumpellyite facies Lushan slate of Miocene age in the western range, and the greenschist facies Chulai Formation of Eocene age in the eastern range from the southern Cross-island highway to around Juisui area (e.g., Chow and Lin, 1974; Stanley et al., 1981; Ho, 1986).

The Tananao Complex crops out as a narrow belt on the eastern side of Taiwan's Central Range (Fig. 4-1a) and bears evidence of polymetamorphism and multiple deformations (e.g., Ernst and Jahn 1987). Traditional classification subdivides the Tananao Complex into the western pre-Cenozoic Tailuko Belt and the eastern Cretaceous to Miocene Yuli Belt (e.g., Ho, 1986; Chen et al., 2017), separated by the Shoufeng Fault (Yen, 1963, F3 in Fig. 4-1), a possibly mega-backthrusting fault (e.g., Zhang et al., 2020). The Tailuko Belt consists of Permian Chiuchu marbles and variegated Mesozoic Kuyuan greenschists (Liou, 1981; Fig. 4-2). The Yuli Belt contains lithologically heterogeneous blueschist-facies rocks in what is referred to as high-pressure (HP) tectonic or exotic blocks (e.g., Liou et al., 1975) surrounded by an intensely deformed schistose unit of lower metamorphic grade (Fig. 4-1b). Three larger exposures of these blocks are the Wanjun, Juisui, and Chinsui Hsi areas (Yen, 1963; Liou et al., 1975). Some petrological pressure-temperature-timing studies and structural analyses (e.g., Yang and Wang, 1985; Tsai et al., 2013; Sandmann et al., 2015; Conand et al., 2020) suggest an allochthonous HP blueschist nappe (~550 °C, 10–12 kbar) emplaced on top of the lower-grade metasedimentary unit along a thrust during a first deformation phase D1 (Zhang et al., 2020). The Yuli Belt's eastern contact with the Chulai Formation of the Backbone Slates (Fig. 4-1b) is strongly deformed and the sharp boundary in terms of lithology and metamorphic grade was interpreted as an unconformity (Stanley et al., 1981; Ho, 1986). However, based on recent detrital zircons ages, from the Yuli Belt metasediments and the northern part of the Chulai Formation, as young as Upper Miocene (e.g., 11.2 ± 0.2 Ma, Mesalles et al., 2020), an

Fig. 4-1: (a) Tectonic map of Taiwan. Traditional nomenclature subdivides the Tananao Complex into the western Tailuko Belt (colored light gray) and the eastern Yuli Belt (colored dark gray) (e.g., Lin and Chen, 2016). (b) Map of peak temperatures in eastern Taiwan obtained from RSCM, compiling various sources. All RSCM were obtained using the calibration of Beyssac et al. (2002) for $T > 330^{\circ}\text{C}$ and low temperatures ($200^{\circ}\text{C} < T < 330^{\circ}\text{C}$) were obtained using Lahfid et al. (2010) marked with “”. (1): Data of Chim et al., (2018) are plotted as arithmetic means of a larger population of data at the localities shown. F2: Chinsui Fault (after Lin and Chen, 2016); F3: Shoufeng Fault (with different interpretations, e.g., Lin and Chen, 2016; Chen et al., 2017); F4: Longitudinal Valley Fault (LVF) (after Shyu et al., 2005).*

alternative trace of Shoufeng Fault has been depicted and the Chulai Formation has been reinterpreted as part of the Yuli Belt (e.g., Chen et al., 2017, 2019; Conand et al., 2020; Zhang et al., 2020; Fig. 4-1b).

Raman spectroscopy of carbonaceous material (RSCM) is being increasingly used as a quantitative geothermometer to estimate maximum metamorphic temperature of the host sediments (e.g., Wopenka and Pasteris, 1993; Yui et al., 1996; Beyssac et al., 2002; Lahfid et al., 2010; Henry et al. 2019). Beyssac et al. (2007) was a pilot study using RSCM at a continuous thermal gradient from the Backbone Slates to the Tananao Complex in Taiwan (Fig. 4-1b). The study encouraged a wider use of RSCM as geothermometer (e.g., Chim et al., 2018; Chen et al., 2019; Conand et al., 2020). However, most past efforts have focused on the central part of the island, and little attention has been paid to the eastern side (Fig. 4-1b). Kouketsu et al. (2019)'s three samples from the Yuli Belt suggested that the results relate not only to peak metamorphic temperature, but also to the pre-metamorphic history and the duration of metamorphic heating. Two samples taken from the Chulai Formation (in Lakulaku and Xinwuliu areas; Fig. 4-1b) have been estimated via RSCM (ca. 370°C ; Beyssac et al., 2007; Chim et al., 2018). The temperature is much lower than those of the adjacent Yuli Belt (ca. $450\text{--}500^{\circ}\text{C}$; Fig. 4-1b), which shows a significant gap between these two units. It is likely that the contact as a fault. These results and conclusions need to be tested with a larger sample set.

The purpose of this study is to investigate the thermodynamic evolution of the metamorphism in the Yuli Belt of Taiwan based on new RSCM data combined with interpretations of the structural deformation of the Yuli Belt and adjacent units. We also discussed the potential influence of our new data on the working tectonic model of the Taiwan arc-continent collision.

Fig. 4-2: Geological map and cross sections (A-B and C-D) in the Lakulaku Hsi and Chinsui Hsi areas. See Fig. 4-1b for location. Parentheses enclosed letters indicate the locations of outcrops in Figs. 4-4, 4-5. The high-pressure metamorphosed units formed allochthonous nappe outliers of a former thrust sheet, emplacing on top of the lower-grade metasedimentary unit.

4.2 Sampling and methodology

To fill the gap in eastern Taiwan, our data complement previous RSCM data from transects of two cross-island highways (Beysac et al., 2007), southern Taiwan (Conand et al., 2020), northern Taiwan (Chen et al., 2019), the Coastal Range (Chim et al., 2018), and the Yuli Belt (Syu, 2009; Kouketsu et al., 2019). Temperatures over 330°C were calibrated using the equation proposed by Beysac et al. (2002) and low temperatures (200°C < T < 330 °C) were obtained using Lahfid et al. (2010) (Fig. 4-1b). Data of Chim et al. (2018) are plotted as arithmetic means of a larger population of data at the estimated localities shown. Our sixteen black metapelites/phyllites samples were collected along selected transects in the Yuli Belt and the Chulai Formation of eastern Taiwan (Fig. 4-1b; Table 4-1; representative microscopic features, Appendix C- Fig.S1). At each sampling site, a careful examination of structural deformation was carried out to systematically measure and characterize ductile deformation by the direction of stretching lineation and associated sense of shear whenever possible (Figs. 4-2, 4-3).

RSCM was used to quantify the degree of thermal alteration of carbonaceous material (CM) within the sampled metasediments. Raman spectra were obtained using corundum polished standard petrographic thin sections, with a thickness of ca. 30 µm. RSCM analyses were performed at the Friedrich Schiller University of Jena using the Horiba LabRam HR Evolution with a focal length of 800 mm and a 532 nm Spectra Physics argon laser. Grains of CM were selected and analyzed one by one with an Olympus microscope mounted on the Raman spectrometer. 31 to 107 particles of CM (with an average of 66.4 for all samples) were collected per sample (Tables 4-1, Appendix C- Fig. S1). The spectra were baseline corrected via LabSpec Spectral Software using a linear baseline in the spectral range of 1100–1800 cm⁻¹, and decomposed to the G-band (1580 cm⁻¹), D1-band (1350 cm⁻¹) and D2-band (1620 cm⁻¹). We evaluated the crystallinity of CM using the parameter R₂, which is the area ratio of D1/(G + D1 + D2). According to the calibration of Beysac et al. (2002), the R₂-ratio shows a linear correlation to peak metamorphic temperature (T) in the range of 330 °C to 640 °C. Standard errors are given for temperature with 1σ. Details on data processing and representative Raman spectra of CM in each sample are provided in supporting materials, respectively (Appendix C- Table S1). Despite the use of the same calibration method, RSCM data obtained by different authors may show slight discrepancies in view of diverse analytical setups and differences in data handling.

Fig. 4-3: Geological map and the cross section E-F of the Xinwuliu Hsi area. See Fig. 4-1b for location. (b): outcrop location in Fig. 4-4. The lower-grade metasedimentary unit of the Yuli Belt is interpreted to thrust on top of the Pilushan/Chulai Formation before the E-vergent refolding.

4.3 Results

RSCM temperature contours are generally along the NNE-strike in the eastern Taiwan Central Range (Fig. 4-7). Compared with RSCM temperatures of other major morphotectonic units in Taiwan (Fig. 4-1a), the Tananao Complex shows higher temperatures between ca. 350 and 550 °C (Fig. 4-1b). The western Tailuko Belt shows average temperatures of c. 450 °C. In its northern part that hosts numerous granitoid intrusions (Fig. 4-1b), temperatures can reach over 500 °C. The peak metamorphic temperatures along the Central and Southern cross island highways show a general eastward increasing trend in the Tailuko Belt (Figs. 4-1b, 4-3). We interpret the Tailuko Belt to be an eastward backfolding and thrusting structure in the orogenic retro-wedge, evidenced by the new developing W-dipping foliations (D3) overprinting earlier E-dipping foliated planes during crenulation (Figs. 4-3, 4-7). The eastern Yuli Belt shows generally maximum metamorphic temperatures between ca. 400 and 550 °C, which is higher than in adjacent units. The peak metamorphic temperatures in the Yuli Belt are complicated due to the intensely multi-deformed schist formations (Fig. 4-2). In places, maximum temperatures in the Yuli Belt exceed 500 °C, specifically in close proximity to three HP metamorphic exotic blocks (Figs. 4-1b, 4-2). We interpret higher temperatures to indicate antiformal structures, and lower temperatures to be synforms in the mostly NW-dipping schistose unit of the Yuli Belt (Figs. 4-2, 4-3). In the Yuli Belt, the northwest-dipping dominant (D3) foliation (Fig. 4-2) refolded the earlier (D2) compositional layering (Fig. 4-4 (a) (c)), and simple shear deformed schists with top-to-the-SE/S kinematic (Fig. 4-5(i)(j)), considered to have accommodated eastward backfolding and thrusting during D3. Temperature transitions across the Shoufeng Fault (e.g., along Shoufeng Hsi and Xinwuliu Hsi, Figs. 4-1b, 3) are gradual, which is in agreement with lithological and fabric transitions in the field. Dip direction and dip of schistose foliations are mostly W- to NW in the Yuli and Tailuko belts and remain constant across the fault (Figs. 4-2, 4-3). Thus, the juxtaposition of the two belts across the Shoufeng Fault may form during an early W-directed transport (D2) before eastward backfolding and thrusting (D3).

Fig. 4-5: Field photos of the Chulai Formation and the Yuli Belt in the Lakulaku area, showing example of ductile shear zone. See Fig. 4-2 for outcrop locations. (e)-(h) are from the contact between the Chulai Formation and the Yuli Belt. (i) and (j) are from the Yuli Belt.

(e) and (f): Veined metapsammitic to metapelitic sediments are intensely deformed and affected by D3 refolding with gradational textural and metamorphic change in the contact zone. Fold axes gently plunge to the north. Location: 23.309016°N, 121.252120°E.

(g): Northwest-dipping low-grade metamorphic slates and thin intercalations of sandstones in the contact zone, showing deformation structures indicative of top-to-the SE shear and layer-parallel extension. Location: 23.309450°N, 121.248937°E.

(h): Structural planes with slickensides. Black arrows indicate the moving direction of the contrary side judged from steps. Northwest-dipping dominant foliation in the contact zone with top-to-the SSE shear sense of the hanging wall. Location: 23.309450°N, 121.248937°E.

(i): Simple shear deformed Yuli Belt schists with top-to-the-SE kinematics. Location: 23.337362°N, 121.217721°E

(j): Quartz veins crosscutting foliation planes in the Yuli Belt CM-rich schists, showing deformation structures indicative of top-to-the S shear. The plunge/trend of quartz stretching lineations in quartz layers is 012/09. Location: 23.345590°N, 121.198246°E.

By contrast, samples from the Backbone Slates, including the western Pilushan Formation and the eastern Chulai Formation, contain much lower RSCM temperatures between 295 and 372 °C (Figs. 4-1b, 4-2, 4-3). The Chulai Formation is significantly different from the adjacent Yuli Belt but shares a number of key features to the Pilushan Formation. (1): The Chulai Formation shows average temperatures of c. 360 °C, within the temperature range of the Pilushan Formation, between 330 and 450°C. (2): Both Chulai and Pilushan formations contain pervasive silvery gray, quartz-rich phyllites and slates with NE/N-dipping in the field (S2 foliation in Fig.4-4; Figs. 4-2, 3). Therefore, we propose a stratigraphic correlation linking Chulai Formation and Pilushan Formation together in the Backbone Slates (Fig. 4-3). (3): The temperature difference between the Chulai Formation and the Yuli Belt reaches ca. 100 °C (e.g., in the cross sections A-B and E-F, Figs. 4-2, 4-3), indicating the contact between these two units as a fault, namely the Chuisui Fault in this study (F2; Figs. 4-1, 4-2, 4-3). The Yuli Belt schist has experienced greenschist to amphibolite facies metamorphism at deeper levels, with higher estimated temperatures than the phyllitic Chulai Formation. On the basis of surface structural data and RSCM data, we interpret the whole Yuli Belt to be a nappe that emplaced on top of the lower-grade Chulai Formation along the Chuisui Fault during a second deformation phase D2. In the field metapsammitic to metapelitic sediments of the ductile contact zone are intensely deformed, with gradational textural and metamorphic change (Fig. 4-5 (a) (b)). The eastward transport direction (D3) is observed in the contact zone, showing deformation structures indicative of top-to-the SE shear (Fig. 4-5), kinematically similar to the Shoufeng Fault. It suggests both the Yuli Belt and the Chulai Formation may experience the same deformation history after D2 deformation.

4.4 Evolution in the eastern Taiwan Central Range

The tectonic evolution and structural position of the Yuli Belt as part of the Taiwan mountain belt is a key element for to understand the preceding subduction and the ongoing arc-continent collision. Metamorphic overprinting and age relations (e.g., Sandmann et al., 2015), RSCM data (e.g., this study; Fig. 4-7), and structural analyses (e.g., Zhang et al., 2020) suggest that the eastern Taiwan Central Range formed during four successive deformation stages, termed D1, D2, D3 and D4 in the following. A kinematic evolutionary shoe-box cartoon (Figs. 4-6, 4-8) is proposed to illustrate the relationship between cooling and erosion during exhumation of the eastern Taiwan Central Range.

Fig. 4-6: Lithosphere-scale kinematic model to explain the origin of the Yuli Belt of Taiwan (modified after Zhang et al., 2020). WF: Western Foothill; HR: Hsuehshan Range; BS: Backbone Slates; TC: Tananao Complex. See text and Fig. 4-8 for further discussion.

Fig. 4-7: RSCM temperature contours in the eastern Taiwan Central Range. Contours are processed by line smoothing (Gaussian Filtering, Sensitivity 3) within major morphotectonic units. Late Cretaceous granitoids intrusions are shown in the northern Tailuko Belt (Yui et al., 2009). Exposure of reset apatite and zircon fission-track ages (after Fuller et al., 2006 and Resentini et al., 2020) supports southward erosion rates are higher in the retro-side of the Taiwan orogen, as also suggested by catchments studies (after Dadson et al., 2003).

D1: HP rock exhumation phase. The HP, blueschist-facies blocks within the Yuli Belt show Mid-Miocene protolith ages (three samples weighted mean of 15.6 ± 0.3 Ma; Chen et al., 2017), about when the South China Sea ceased spreading (ca. 15.5 Ma, Taylor and Hayes, 1983; Sibuet et al., 2002) and started subducting under the Philippine Sea Plate (Huang et al., 2006). The crystallization ages perhaps provide the single most solid maximum age for Taiwan mountain building initiation. HP blocks subducted reaching peak-P-T conditions (e.g., Beyssac et al., 2008; Tsai et al., 2013) and exhumed portions of crust and mantle along the HP thrust on top of the lower-grade metasedimentary unit of the Yuli Belt (F1; Zhang et al., 2020; Fig. 4-8). The higher RSCM temperatures of the metasediments surrounding the HP blocks (Fig. 4-7) are a result of additional thermal overprint either by the HP metamorphic blocks or by a retrograde overprint under amphibolite- to higher greenschist-facies conditions along the exhuming F1 thrust. Both possibilities suggest that the post-D1 metamorphic history of the Yuli Belt and the HP metamorphosed blocks is similar.

D2: W-ward folding and thrusting phase. Recent chronological constraints argue for the Yuli Belt metasedimentary unit and the Chulai Formation share the same continental affinity zircon U-Pb age populations as young as Upper Miocene (ca. 11 Ma, Chen et al., 2017; Mesalles et al., 2020). However, different lithologies and different maximum metamorphic temperatures (Figs. 4-1, 4-7) between the Yuli Belt and the Chulai Formation contradict this interpretation. In this study, the correlation with the Eocene to Upper Miocene age has been assigned to the sediments in Chulai and Pilushan Formations. Rift-related half-grabens generally accumulated via Eocene-Miocene fluvial to outer shelf deposits over 6 km thick, and derived from the Eurasian continent (Yu et al., 2013) (Fig. 4-6). RSCM temperatures, lithological-, and fabric-transitions are constant across the Shoufeng Fault (Figs. 4-1b, 4-4; Zhang et al., 2020). This indicates that the juxtaposition of the Yuli Belt and the Tailuko Belt (unconformably covered by Pilushan Formation) across the Shoufeng Fault formed during early W-directed transport (D2 phase; Figs. 4-6, 4-8). The Yuli Belt including the former allochthonous HP metamorphic material was thrust on top of the Pilushan/Chulai Formation along F2 (Chinsui Fault).

D3: Erosional E-ward backfolding and backthrusting phase. The Yuli Belt appears as a large synformal structure with top-to-the-SE shear at the footwall of Shoufeng Fault (F3), in contact with the Tailuko Belt to the west as part of the hanging wall of the F3 (Fig. 4-8). The majority of the HP metamorphic material was eroded during this deformation stage with the exception of small relic blocks in the center of the synformal structure (e.g., cross section C-D; Fig. 4-2). Notably the trace of the F2 contact is poorly preserved and was only reported in the Xinwuliu Hsi area along the Yuli Belt (Stanley et al., 1981). A possible explanation for this might be that the Chulai Formation underwent essentially the same deformation history as the

Fig. 4-8: Conceptual kinematic model to explain the Yuli Belt exhumation and structural position (modified after Zhang et al., 2020). The correlation with the Eocene to Upper Miocene age has been assigned to the sediments in Chulai and Pilushan Formations. D1 stage: high-pressure metamorphic rock thrust over the Yuli Belt metasedimentary unit along the F1 (HP thrust); D2 stage: W-ward thrusting of Yuli Belt onto Tailoko Belt along F2 (Chinsui Fault); D3 stage: E-ward backfolding and backthrusting along F3 (Shoufeng Fault), in combination with later erosion; D4 stage: F4 (LVF, Longitudinal Valley Fault) possibly overprinted the earlier structures. See text for further discussion.

Yuli Belt (in D3-D4 phases), as indicated by sedimentary relationships and structural considerations (Ho, 1986; Fig. 4-5). Thus, the emplacement of the higher-grade metasedimentary Yuli Belt as a nappe on top of the lower-grade Chulai Formation was most likely a separate step prior to the D3 refolding and backthrusting (Figs. 4-3, 4-5). Future research should hence focus on kinematics and fault-related fabrics along the contact to test our model.

D4: Erosion phase. RSCM contours (Fig. 4-7), the continental margin, and the Luzon arc of the Philippine Sea Plate are subparallel, nourishing an initial collision that was simultaneous along the NNE-strike. Apatite and zircon fission-track ages (Fuller et al., 2006; Resentini et al., 2020) and catchments studies (Dadson et al., 2003) both imply that erosion rates in the Backbone Slates were systematic higher towards the south (Fig. 4-7). F4 (Longitudinal Valley Fault) possibly overprinted the earlier structures in combination with later erosion.

4.5 Conclusions

We applied new RSCM temperature measurements in metasedimentary rocks of the Yuli Belt and the Chulai Formation. Peak metamorphic temperatures in the greenschist-facies metasediments, when compiled with published data, support systematic spatial variations across the eastern Taiwan Central Range. The metasedimentary unit of the Yuli Belt shows higher temperatures of c. 400–550 °C than the westerly and easterly adjacent units of the Tailuko belt and the Chulai Formation. Close to allochthonous high pressure blocks, the metasediments of the Yuli Belt indicate maximum metamorphic temperatures of > 500 °C. The temperature difference between the Yuli Belt and the Chulai Formation exceeds 100 °C. Therefore, it appears more likely that the contact between the Yuli Belt and the Chulai Formation is a fault contact (F2; Chinsui Fault in this study), suggesting an overall synformal structural position of the Yuli Belt, with respect to the easterly and westerly adjacent units. We suggest that this synformal geometry, as results of backfolding during the D3 phase of the Taiwan Central Range.

Chapter 5

General Conclusions and Outlook

The aim of my PhD thesis is to better understand improperly understood aspects of the Taiwan orogeny and accretion, subduction and collision processes. In this dissertation, based on results from regional mapping and structure analysis, three crustal-scale geological cross-sections of the Taiwan mountain belt were constructed, providing quantitative estimates on the amount of shortening that the former passive margin of the South China Sea underwent prior to its involvement in arc-continent collision. Four cross sections in a local scale across the Taiwan's metamorphic Yuli Belt were constructed, taking new outcrop- to microscope-scale structural observations from several river-transects into account. Analyses of the whole-rock geochemistry study on the high-pressure rocks and analyses of the Raman spectroscopic geothermometry on the metasediments were conducted in order to constrain tectonic settings and palaeogeographic reconstructions. The following conclusions can be drawn, with respect to the three questions presented in Chapter 1.

(A) This study provides new surface geological mapping and three transects across the entire Taiwan. The structure of Taiwan orogen was interpreted to be two deformation types (D1 and D2) with three basement imbricates. D1 type is an imbricate westward fold-and-thrust system, which develops in the Coastal Plain, Western Foothills, Hsuehshan Range and Backbone Slates. D2 type is an east-facing backfolding and backthrusting system in the eastern Central Range, leading to the development of a second, vertical to steeply W-dipping younger cleavage (S2) that overprinted older nappe-stacking related foliations (S1). Three crustal scale basement imbricates (the Infra-Pilu Tunnel Thrust basement unit, the Pilu Tunnel Thrust basement, and the Shoufeng Fault basement unit) are bounded by three basal thrusts and the Longitudinal Valley Fault. Following nappe stacking accretion, these basement units were later involved in orogen-scale D2 backfolding and backthrusting in structural architecture. Based on three balanced and restored cross sections, we estimate the minimum shortening of the former passive margin of Eurasia to be ~120 km in the central and ~140 km in the south, which is consistent with the underlying unfolded passive margin tomography. Over half of the basement, on top of which the accreted material was initially sitting, has entered subduction. The restored cross sections also reveal a system of subducting rift basins on the continental shelf with bounding normal faults that have been reactivated during subduction. In the paleogeographic

maps, the Eurasian passive margin likely formed a slightly eastward-convex salient prior to plate convergence that created the Taiwan orogen.

(B) Three new cross-sections across Taiwan's Yuli Belt were constructed in a local scale, taking new outcrop- to microscope-scale structural observations from several river-transects into account. The Yuli Belt was affected by at least three successive deformation phases (namely D0 to D2). High-pressure metamorphic units were emplaced on top of metasedimentary units of Yuli Belt along a thrust during the first deformation D0. This assembly was later thrust over Eurasian-derived series of the Tailuko Belt along the Shoufeng Fault during D1, suggested by (rarely preserved) downplunging stretching lineations on W- to NW-dipping foliation planes. E-vergent open to tight folds throughout the Yuli Belt with W- to NW-dipping axial planes were produced by the D2 phase, refolding earlier foliations as well as the D0 nappe contact, during which also the blueschist- facies and metasedimentary units were folded. This phase might be related to a top-E back-thrusting and a reorientation of the Shoufeng Fault from an initially E-dipping to a presently W-dipping contact, for which we present new evidence. High-pressure metamorphic units were interpreted to form erosional relics of nappe outliers of a formerly more contiguous thrust nappe that hosts part of the suture zone in Taiwan. The whole-rock geochemical fingerprint of high-pressure metamorphic rocks is in the MORB tectonic settings of the South China Sea, and could display the effects of metasomatism of their mantle source by slab-derived fluids and alteration from low-temperature seafloor in the subduction zone. Therefore, the blueschist-facies metamorphic unit most likely represents a mid-Miocene fragment of oceanic crust and mantle issued in the South China Sea before having been subducted, exhumed and 'sandwiched' between the Tailuko Belt and the easterly adjacent Coastal Ranges derived from the Philippine Sea Plate.

(C) New Raman spectroscopy of carbonaceous material (RSCM) temperatures in from metasedimentary rocks of the Yuli Belt and the Chulai Formation were applied. Peak metamorphic temperatures in the greenschist-facies metasediments, when compiled with published data, support systematic spatial variations across the eastern Taiwan Central Range. The metasedimentary unit of the Yuli Belt shows higher temperatures of c. 400–550 °C than the westerly and easterly adjacent units of the Tailuko belt and the Chulai Formation. Close to allochthonous high pressure blocks, the metasediments of the Yuli Belt indicate maximum metamorphic temperatures of > 500 °C. The temperature difference between the Yuli Belt and the Chulai Formation exceeds 100 °C. Therefore, it appears more likely that the contact between

the Yuli Belt and the Chulai Formation is a fault contact (Chinsui Fault), suggesting an overall synformal structural position of the Yuli Belt, with respect to the easterly and westerly adjacent units. We suggest that this synformal geometry, as results of the backfolding deformation phase of the Taiwan Central Range.

There are some perspectives which are worth to be studied in the future regarding several aspects of this thesis. The most important point concerns the Yuli Belt of Taiwan. In the Yuli Belt, protolith ages of blueschists are ca. 15 Ma (e.g., Chen et al., 2017; MORB-type, this study); protolith ages of (meta)gabbros/plagiogranite are ca. 15-17 Ma (MORB-type geochemistry; Lo 2018); only one age on epidote amphibolite was estimated at ca. 79 Ma (MORB-type; Jahn et al., 1981); and no protolith age constraints from serpentinite blocks. More accurate structural and geochronological data, particularly on the ages of magmatic protoliths and of high-pressure metamorphism are necessary, in order to constrain the deformation-metamorphism relations and the exhumation mechanism of Yuli Belt blueschists. This, in turn, will facilitate our understanding of the models of fore-arc subduction.

Appendix A (Chapter 2)

Figure S1:

Deep crustal interpretation on the cross section across Central Cross-island Highway of Taiwan (A-A') based on the V_p tomography (Wu Y.-M. et al., 2008a). Crust-mantle interfaces constrained from a 3D-model employing seismological data after Ustaszewski et al. (2012). See Fig. 2-2 for section trace A-A'.

Figure S2:

Deep crustal interpretation on the cross section across central Taiwan (B-B') based on the V_p tomography (Wu Y.-M. et al., 2008a). Crust-mantle interfaces constrained from a 3D-model employing seismological data after Ustaszewski et al. (2012). See Fig. 2-2 for section trace B-B'.

Figure S3:

Deep crustal interpretation on the cross section cross Southern Cross-island Highway of Taiwan (C-C') based on the V_p tomography (Wu Y.-M. et al., 2008a). Crust-mantle interfaces constrained from a 3D-model employing seismological data after Ustaszewski et al. (2012). See Fig. 2-2 for section trace C-C'.

Appendix B (Chapter 3)

Figure S1:

P-T diagram (simplified after Maruyama et al. 1986) showing calculated metamorphic conditions and *P-T-t* paths suggested for high-pressure rocks in the Yuli belt with various metamorphic parageneses, as well as for a chlorite-mica schist from the metasedimentary unit (bold path-8). Type-I ($\text{Amp} + \text{Qz} + \text{Ep} + \text{Gar} + \text{Chl} + \text{Rt/Ttn}$); Type-II: $\text{Pg} + \text{Amp} + \text{Qz} + \text{Ep} + \text{Gar} + \text{Chl} + \text{Ttn} + \text{Bt} + \text{Mag}$), Type-III ($\text{Amp} + \text{Qz} + \text{Ab} + \text{Ep} + \text{Gar} + \text{Rt} + \text{Hem} + \text{Ttn}$), and Type-IV ($\text{Amp} + \text{Ep} + \text{Pg} + \text{Qz} + \text{Ab}$) are from Tsai et al. (2013). Mineral abbreviations follow those of Whitney and Evans (2010). Other abbreviations are Zeo, zeolite facies; PP, prehnite-pumpellyite facies; PA, pumpellyite-actinolite facies; PrA, prehnite-actinolite facies; GS, greenschist facies; EA, epidote-amphibolite facies; AM, amphibolite facies; BS, blueschist facies; AEC, amphibole eclogite facies. Figure S2:

The samples localities of the whole-rock geochemistry analysis.

Table S1:

Summary of deformation phases of the Yuli Belt metasediments from previous studies

Reference	Area	Method	Deformation phases & age (if any)
Stanley et al. 1981	Southern Cross island highway	Schistosity and folding crosscutting relationships; Lithological correlations	S1 = Cryptic S2 = Penetrative axial surface F2 = West vergent folds and faults S3 = NE strike; W dipping; Crenulation cleavage F3 = East verging; hinge plunge NE S4 = NE strike; NW dip; F4 = minor folds deforming F5 & F6 = kink folds; variable orientation; flexing of dominant schistosity
Pelletier and Hu, 1984	Southern Cross Island Highway; East & South Taiwan	Structural analysis	F0 = southward directed slumps D1 = EW to NW-SE compression; S1 =Axial planar T1 = west vergent thrust F2 = kink-folds verging to the East, backfolding S2 = Crenulation cleavage F3 = North verging, E-W axis
Hu and Tsan 1984	Southeastern Taiwan, Central Range	Structural and sedimentological analysis	F0 = NS (EW depositional folds) S2 = NWW-SEE (NS-overturned tight folds & cleavage) D3 = bending of S2 cleavage
Faure et al 1991	Central & Southern cross island highway	Microstructural analysis & synthesis of previous works	S1 = fracture cleavage (in the W. slate belt) F1 = overturned to the west (in slate belt) L1 = non-coaxial, top to the NW shear sense D2 =3.5 Ma (Pelletier and Stephan, 1986) F2 = overturned to the E., axis trend 100N (back folding); S2 =axial planar crenulation F3 = axis S dipping D4 = Normal faulting
Clark et al. 1992	Northern & Southern Cross Island Highway	Microstructural analysis (syntectonic fibrous growth orientation)	D1; D2; D3=D2; D4 of Stanley et al., 1981 S1 = dipping ~40SE; L1 = updip; Clockwise rotation of elements + asymmetric folds and boudins → non-coaxial (simple shear) S2 = crenulation cleavage with fanning structure F2 = west vergent folds & axis dipping ~35° to the NE L2 = indicate fold-axis parallel extension & left-lateral shear Normal Faults = σ_3 plunge towards the NE, parallel to S2 S3 = crenulation cleavage dipping NW, locally transposing S2 (in the east)
Fisher 1999 & Fisher et al. 2002	Easternmost Backbone Slates	Structural and microstructural analysis	S2 = local crenulation, moderately W dipping F2 = axis gentle NE plunging. L2 = moderately NE dipping Normal Faults = late W-dipping
Yeh 2004	Eastern Central Range	Structural and microstructural analysis	S0 = 37/096, overturned S1 = 31/075 strong pervasive slaty cleavage S2 = 36/308 pervasive foliation F2 = kink-folds verging to the East; backfolding S3 = 27/215, slaty cleavage F3 = kink-folds verging to the North; fold axis 21/025 S4 = weak crenulation cleavage Normal Faults = 45/045, 45/205, top-to-NE/SW shear
Ho and Lo 2015	Shoufeng Hsi (Wanjung area)	Structural and microstructural analysis	S1 = commonly destroyed; in the microlithon S2 = moderately NW dipping F2 = east-vergence isoclinal folding S3 = sub-horizontal axial plane cleavage F3 = recumbent folds; fold hinge plunge NW
Ho 2015	Southern Cross Island Highway	Structural and microstructural analysis	S1; S2; S3 of Ho and Lo 2005 Normal Faults
Mondro et al. 2017	Eastern Central Range (Eocene slates)	Syntectonic fibrous growth orientation	S2 of Fisher et al. 2002 bulk coaxial strain and lateral extrusion effects

Appendix C (Chapter 4)

Table S1: RSCM data of the sixteen samples with point measurements. All peak metamorphic temperatures (T) were obtained using the calibration of Beyssac et al. (2002).

int: band intensity; FWHM: full width half maximum; $R1 = (D1/G)$ (peak height ratio); $R2 = D1/(G+D1+D2)$ area

Sample 1: YQ17-3

Figure S1:

Representative microscopic features of black schists. Images on the left are in plane-polarized light, and on the right are in cross-polarized light. Abbreviations: *Ab* = albite; *Cal* = calcite; *CM* = carbonaceous material; *Chl* = chlorite; *Ep* = epidote; *Qz* = quartz; *Tlc* = talc; *Tin* = titanite; *Wm* = white mica.

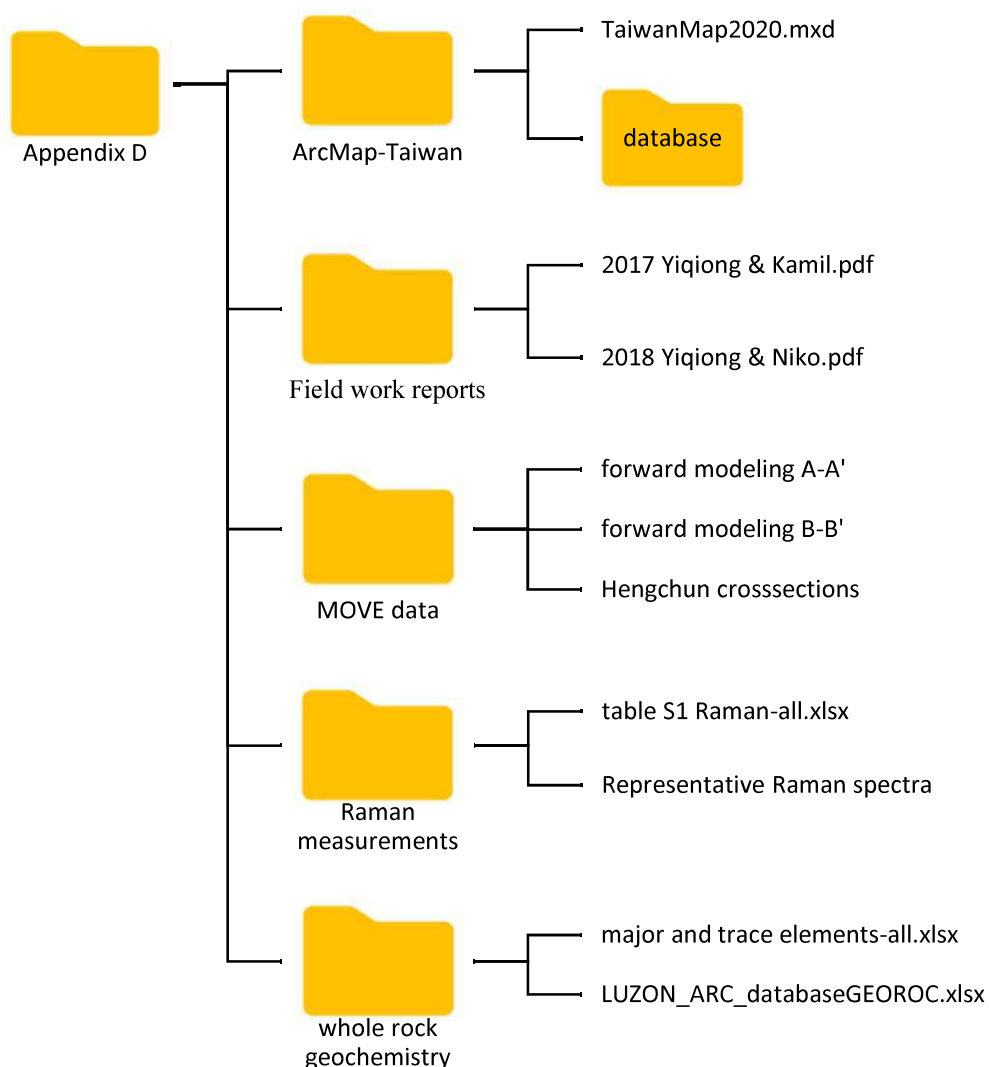

Appendix D (Digital supplemental material)

The digital supplemental material in the attached CD-R is complementary to this dissertation. It provides a GIS database with Taiwan maps, Digital Elevation Models (DEM), and outcrop data, field work reports, MOVE databases with cross sections, Raman measurements with representative spectra, and whole-rock geochemistry data. It also includes the published RSCM (Raman spectroscopy of carbonaceous material) data, Luzon arc geochemistry data for comparison.

File order:

Descriptions:

The GIS database of this dissertation contains maps of Taiwan (in the scales of 1:500 000 and 1:50 000), DEM data of Taiwan and surrounding areas (with the spatial resolution of 40 metres),

outcrop data (with field measurements of several times in Taiwan from 2008 to 2018), and sample location. Our RSCM temperature data as well as the published data (e.g., Beyssac et al., 2007; Conand et al., 2020; Chim et al., 2018; Syu, 2009; Kouketsu et al., 2019) are also provided in the GIS database as a supplement for Chapter 4.

I took two times of field works in Taiwan with my PhD supervisor Prof. Dr. Kamil Ustaszewski, in the year of 2017 and with my second supervisor Prof. Dr. Nikolaus Froitzheim in the year of 2018. The field work reports provide the itinerary of daily trips, outcrop locations, measurements, maps, photos with descriptions. The reports are as supplements for Chapters 2, 3, and 4.

MOVE databases consist of three modelings. (1): Forward modelling of the cross section across Central Cross-island Highway of Taiwan (A-A') in Chapter 2. (2): Forward modelling of the cross section across central Taiwan (B-B') in Chapter 2. (3): Maps, cross sections and measurement database of the Hengchun Peninsula are an independent section of my PhD research work which is not presented in this dissertation.

The whole-rock geochemistry data contains major elements and selected trace elements. Both were measured using X-ray fluorescence (XRF) and, after total digestion, inductively coupled plasma-optical emission spectrometry (ICP-OES) and inductively coupled plasma-mass spectrometry (ICP-MS) at the Institute of Geological Sciences at the Friedrich-Schiller University Jena. The Luzon volcanic arc geochemistry data were taken from the database GEOROC (Geochemistry of Rocks of the Oceans and Continents; <http://georoc.mpch-mainz.gwdg.de/georoc/>) for comparison.

The dissertation-related published publication is also enclosed in the CD-R:

Zhang, Y., Tsai, C.-H., Froitzheim, N., Ustaszewski, K. (2020): The Yuli Belt in Taiwan: part of the suture zone separating Eurasian and Philippine Sea plates. *Terrestrial, Atmospheric and Oceanic Sciences*, 31, 415-435, doi: 10.3319/TAO.2020.06.28.01

Acknowledgements

First, I would like to sincerely thank **Prof. Dr. Kamil Ustaszewski**, my supervisor, for providing me this interesting work. I still remember our first skype-meeting on 24.11.2015, regarding the Taiwan project and the CSC application, at which time he was the reason that I decided to come to Jena. After these four years, I am completely convinced that I made a good decision and what I learnt is far beyond my expectation. His generous supervision made me feel comfortable in pursuing different subjects, and during my research, his immense knowledge and constant encouragement profoundly influenced and inspired me. With his generous patience, I can gradually grow up and broaden my view in the field of structural geology.

I am especially indebted to **Prof. Dr. Nikolaus Froitzheim** from Rheinische Friedrich-Wilhelms-Universität Bonn and **Prof. Dr. Chin-Ho Tsai** from National Dong Hwa University, Taiwan. They supervised me in the fieldwork and during the paper submissions not only as scientific-project partners, but also as generous friends. I also wish to acknowledge Master students (**Chiao Liu, Wen-Han Lo, Chih-Ying Yeh, Dominikus Deka Dewangga, and Yu-Wei Chang**) from National Dong Hwa University for fieldwork assistance.

Many thanks also go to my colleagues (**Dr. Christoph Grützner, Philipp Balling, Georg Löwe, Benjamin Schmitz, Mjahid M. Zebari, Chris Salomon, Madeline Richter, Dr. Taufeeq Dhansay and Dr. Payman Navabpour**) in the JST working group for their kindness and constant emotional support. I greatly appreciate them who offered the guidance and support over the years. Moreover, I thank **Dr. Kilian Pollok, Prof. Dr. Lothar Viereck, Dr. Sami Nabhan, Dr. Stefan Kiefer, and Dr. Arno Märten** for valuable discussions on lab experiments. I thank **Frank Linde, Sandra Urban, Michael Ude, and Dr. Dirk Merten** for sample preparations. The great working environment established the crucial basis of all the research works. I wish the nice memories would always last and continue in the IGW building.

The final words of thanks must be reserved for my **family**. My boyfriend Hongpu Zhou supported me whenever I needed him, and I thank you with all my heart. I would like to thank my parents for supporting me spiritually throughout my life. No matter where I am, on the way to chase my dream, they are always the strongest backing of mine.

This dissertation and my doctor study were funded by the Deutsche Forschungsgemeinschaft (DFG; grant 380155214) as well as the China Scholarship Council (CSC; number 201606400062).

Selbstständigkeitserklärung

Ich erkläre, dass ich die vorliegende Arbeit selbständig und unter Verwendung der angegebenen Hilfsmittel, persönlichen Mitteilungen und Quellen angefertigt habe.

Jena, den 10. Sep. 2020
